Optimal Income Taxation with Spillovers from Employer Learning

Ashley C. Craig*

August 2021

Abstract

I study optimal income taxation when human capital investment is imperfectly observable by employers. In the model, Bayesian inference about worker productivity compresses the wage distribution, lowering the private return to human capital investment. An externality arises: given the same information, employers are more optimistic about each individual if workers are generally more productive. The significance of this externality hinges on the accuracy of employers’ beliefs and the responsiveness of human capital. For the US, taking it into account lowers optimal marginal tax rates for most workers, reducing them by a maximum of 9-13 percentage points between $50,000 and $100,000.

Thanks: I am indebted to my advisors, Roland Fryer, Lawrence Katz, David Laibson and Stefanie Stantcheva. I am also grateful for valuable comments and suggestions from mentors, colleagues and interviewers, including: Lisa Abraham, Ole Agersnap, Joseph Altonji, Gaurab Aryal, Alex Bell, Pierre Boyer, Raj Chetty, Oren Danieli, Adriano Fernandes, Edward Glaeser, Benjamin Golub, Nathaniel Hendren, James Hines, Albert Jan Hummel, Louis Kaplow, Dirk Krueger, Hyunjin Kim, Musab Kurnaz, Jonathan Libgober, Weiling Liu, Benjamin Lockwood, Philip Marx, Gregory Mankiw, David Martin, Namrata Narain, Casey Rothschild, Dominik Sachs, Heather Sarsons, Joel Slemrod, Aleh Tsyvinski and Matthew Weinzierl. Thanks also to participants at many Harvard seminars and lunches; seminars at ANU, Bocconi, Michigan, UCLA, the University of Melbourne, Monash, UNSW, the University of Sydney, Penn Wharton, and Yale; and talks at the Young Economists Symposium, NBER Summer Institute, the NTA, IIPE, CESifo Public Economics, WEAI, SED and the Virtual Australian Macro Seminar.
Funding and Conflict of Interest: Financial support from the University of Michigan, Harvard University, the Harvard Kennedy School Women and Public Policy Program, and a James M. and Cathleen D. Stone Ph.D Scholarship from the Multidisciplinary Program in Inequality & Social Policy at Harvard University is gratefully acknowledged.
1 Introduction

Employers base hiring and remuneration decisions on imperfect information. When evaluating workers, they rely on noisy correlates of productivity such as references, academic transcripts, and job market papers. Although employers’ beliefs about a given worker become more accurate over time, there can be a substantial delay before the worker’s wage reflects her marginal product (Farber and Gibbons 1996, Altonji and Pierret 2001, Lange 2007, Kahn and Lange 2014). Until then, employer inference based on imperfect information compresses the wage distribution. As a result of this compression, the present discounted private return to raising one’s productivity is lower than the social return.

In this way, rational inference by employers introduces a positive externality from human capital investment. Intuitively, a student who studies harder obtains higher future wages by improving her test scores, recommendations, and other indications of her ability. But with imperfect employer information, she also benefits from the hard work of other similar students: if her peers were to invest more, employers would tend to look more favorably on her as well.\footnote{This suggests that an encounter with one worker will affect assessments of other observably similar workers. Sarsons (2018) shows this occurs, although her results are hard to reconcile with full rationality.} Her peers do not internalize this spillover when choosing how hard to work, and invest less than is socially optimal. This principle applies to learning by any worker while at high school or college, and to investments later in life.

I study the role of income taxation to correct this type of externality. First, I develop a model of optimal taxation with imperfectly observable human capital investment. Next, I show with a simple example how Bayesian inference by employers compresses the wage distribution, driving a wedge between the private and social returns to investment. The optimal tax rate is lower to correct for the implied externality. Third, I generalize to non-linear taxation, and show that the downward adjustment to marginal tax rates is largest at intermediate levels of income. Finally, I calibrate the model to match empirical moments from the United States. Taking into account the human capital spillover reduces optimal marginal tax rates by a maximum of 9-13 percentage points at around 50,000 to 100,000 dollars of income, with little change in the tails of the income distribution.

After observing her investment cost, each worker in my model makes an imperfectly observable investment in human capital, which determines her productivity. Employers cannot directly observe the worker’s true productivity level. Instead, they infer it based on a noisy but informative signal, combined with a prior belief. As a direct consequence of Bayesian inference by employers, every worker’s equilibrium wage is a weighted average of her own productivity and the productivity of other similar workers. An increase in investment by one group of workers therefore has the side effect of altering employers’
perceptions of other workers who send similar signals.

Taxation in this model has an effect on welfare that is not present in classic models of income taxation (e.g., Mirrlees 1971). When investment in human capital is depressed by higher taxes and productivity falls, employers become less optimistic, and pay workers a lower wage in equilibrium given the same information about their productivity. Individual workers do not take this into account. This is in addition to the usual fiscal externality, which arises because workers ignore the effects of their decisions on government revenue. Since the externality introduced by imperfect employer inference adds to the cost of taxation, taking it into account pushes toward lower optimal marginal tax rates.

The core insights of my model apply more generally. For example, asymmetric employer learning leads to monopsony power for firms, which gives them an incentive to invest in their workers (Acemoglu and Pischke 1998); but imperfect employer information still leads to underinvestment in skills. Similarly, I show in Appendix A that introducing a motive for employers to screen their workers using contracts specifying both labor supply and a wage (e.g., Stantcheva 2014) causes utility rather than wage compression, but still undermines the incentive for workers to invest in human capital.

Using a simple example with linear taxation, I demonstrate how rational employer inference based on imperfect signals causes compression of workers’ wages toward the average level of productivity. This flattens the relationship between productivity and remuneration, introducing a wedge between the private and social returns to investment. Relative to a model with perfect employer information, the optimal tax is therefore lower; this correction is larger if employers have less precise information about their workers’ productivity, or if productivity is more responsive to taxation. In the special case in which all agents receive equal social welfare weight, the optimal tax is always negative, reflecting only the efficiency motive for intervention.

When I allow for non-linear taxation, imperfect employer information introduces a novel effect of a small change to the tax schedule, which I refer to as the belief externality: every worker who changes her investment decision also shifts employers’ beliefs, which in turn affects the wages and welfare of others. Less accurate employer information makes this externality larger, and pushes toward lower taxes. This is in addition to the two classic effects of income taxation: the mechanical effect from the transfer of consumption from high-income workers to low-income workers; and the fiscal externality, which arises because individuals ignore the impact on government revenue of re-optimization of their human capital investment and labor supply decisions.

The welfare impact of the belief externality is greatest at intermediate incomes, which

---

2In Section 4, I show how investment can also hurt others in some cases, although not in simple examples.
contributes to a “U” shape of the optimal marginal tax schedule.³ There are two steps to understand this result. First, a given spillover in wages has a larger effect on consumption for higher-income workers, because they supply more labor. Second, as incomes rise even further, social welfare weights decline toward zero. In turn, this means that a given change in consumption has little effect on social welfare at the highest levels of income.

My results also highlight how the belief externality can be decomposed into two components of opposite sign and different incidence. When a worker invests more, her higher productivity raises the wages of workers who send signals most similar to her own. However, she hurts workers whose signal distributions are concentrated in regions where her own distribution changes the most. The reason for this negative effect is that she becomes more likely to send high signals where her productivity lowers the average conditional on that signal, and less likely to send low signals where she had raised the average. Only in special cases – such as the simple example with linear taxation, where responses are uniform – does the net effect have to be positive everywhere.

To quantify the belief externality, I calibrate my model to match the United States wage and income distributions, evidence on the gap between the private and social returns to productivity, and estimates of the elasticities of wages and labor supply. To calibrate the externality itself, I start with estimates of the speed at which employers learn about worker productivity. Then I use these estimates to calculate how much of the present discounted return to productivity a worker captures when she becomes more productive, taking into account how wages vary over the lifecycle. In addition, I use data from the National Longitudinal Survey of Youth (NLSY79) to show that there is stronger evidence of learning among low-productivity than high-productivity workers.

Taking into account the belief externality significantly reduces optimal marginal tax rates for most workers. As predicted theoretically, the downward adjustment to taxes is concentrated at moderate-to-high levels of income, with little change to the marginal tax rates of workers with the lowest and highest incomes. These qualitative insights are robust, but the quantitative importance of the belief externality hinges on the accuracy of employers’ beliefs and the responsiveness of human capital investments to taxation.

When I extend the model to incorporate formal education, an education subsidy is possible. However, such a subsidy is a poorly targeted instrument to correct the externality from unobservable investment. While it does raise overall investment in human capital, it

³The standard trade-off between equality and efficiency already produces a “U” shape, given the shape of the income distribution typically estimated (Diamond 1998). Raising the marginal tax rate at a given income transfers resources from those above to those below that level, but distorts decisions locally. The “U” shape arises because the efficiency cost increases at low incomes as the density of income rises; it then decreases at high incomes, as the density falls. This shape is amplified by the forces in my model.
does so at the cost of distorting its composition toward formal education. Furthermore, if
the two types of investment are correlated, workers invest too much in formal education
because it acts as a signal of unobservable investment. On net, the mechanisms in this
paper therefore push toward lower rather than higher subsidies for formal education.

If employers can categorize workers based on exogenous characteristics such as race or
gender, my model implies that they will statistically discriminate in any situation in which
the equilibrium productivity distribution varies by group.4 I show how discrimination
may motivate the planner to set group-specific marginal tax rates if differences in the size
of the belief externality cause the private return to increasing one’s productivity to differ
across groups. For example, there is evidence to suggest a lower return to skill for black
workers than white workers (Bertrand and Mullainathan 2004, Pinkston 2006).

**Connections in the Income Taxation Literature**

This paper builds on a rich literature studying optimal income taxation, the modern
analysis of which began with Mirrlees (1971).5 In these models, a social planner seeks to
redistribute resources from high skill to low skill workers. A trade-off between equity and
efficiency arises because workers’ skill levels are not directly observable by the planner.
Redistribution must therefore occur via a tax on earnings, which distorts decisions.

My model connects to a growing strand of this literature in which wages are deter-
dined by markets (Hungerbühler, Lehmann, Parmentier and Van Der Linden 2006, Ales,
The closest connection is to models in which firms do not directly observe worker pro-
ductivity. However, the literature has focused on cases in which worker skill is fixed.
Andersson (1996) studies taxation in a two-type pure signaling model; and Spence (1974)
examines signaling with perfectly inelastic labor supply. Stantcheva (2014) and Bastani,
Blumkin and Micheletto (2015) analyze the screening problem that arises when labor disu-
tility is related to worker productivity, so that working long hours signals high ability.
Most similar in spirit, Hedlund (2018) studies bequest taxation in a model with a similar
belief externality, but with binary investment and no redistributive motive for taxation.

The second key connection is to models in which workers’ skills are attained via in-
vestment in human capital (Bovenberg and Jacobs 2005, Jacobs 2005, Jacobs 2007, Boháček

---

4 My model is a generalization of classic models of statistical discrimination. Pioneered by Phelps (1972)
and Arrow (1973), such models rely on imperfect observability of productivity to explain employers’ use
of a worker’s group identity. Contributions include Aigner and Cain (1977), Coate and Loury (1993), Moro

5 Subsequent work (Diamond 1998, Saez 2001) has enriched our understanding of Mirrlees’ original re-
sults, and has extended them to incorporate extensive margin labor supply responses (Saez 2002), lifecycle
concerns (Albanesi and Sleet 2006, Farhi and Werning 2013, Golosov, Troshkin and Tsyvinski 2016),
rent-seeking effects (Piketty, Saez and Stantcheva 2014), occupational choice (Gomes, Lozachmeur and
Pavan 2018), and migration (Simula and Trannoy 2010, Lehmann, Simula and Trannoy 2014).

Finally, the paper connects to the literature on optimal income taxation with general equilibrium externalities (e.g., Stiglitz 1982, Rothschild and Scheuer 2013, Rothschild and Scheuer 2016, Sachs, Tsyvinski and Werquin 2019, Lockwood, Nathanson and Weyl 2017), and to the broader literature on human capital externalities (Moretti 2004, Kline and Moretti 2014, Nix 2020). However, the aggregate production function is linear in my model. More importantly, the belief externality in this paper has local incidence: rather than production complementarities between dissimilar types, the spillovers here arise because investment by worker changes perceptions by employers about others who are similar. This distinction is important in determining the shape of the optimal tax schedule.

2 A Model of Optimal Taxation with Employer Learning

Let there be a fixed tax schedule $T$. This induces a game between a single worker and several identical firms, indexed by $j \in J$ with $|J| \geq 2$. The timeline is shown in Figure 1. Nature first distributes a cost of investment $k \in K \subseteq \mathbb{R}^+$ to the worker, with cumulative distribution $G(k)$. After observing $k$, the worker invests $x \in \mathbb{R}^+$ at utility cost $kx$, yielding productivity $q = Q(x)$ where $Q'(x) > 0$, $Q''(x) < 0$, $Q(0) = 0$ and $\lim_{x \to 0} Q'(x) = \infty$.6

<table>
<thead>

<th>Worker accepts highest wage</th>
<th>Payoffs realized</th>
</tr>
</thead>
<tbody>
<tr>
<td>Worker invests</td>
<td>Firms offer wages</td>
<td>Worker supplies labor</td>
<td></td>
</tr>
</tbody>
</table>

Nature then distributes a signal of productivity to the worker and all firms.7 Specifically, let $\theta \in \Theta \subseteq \mathbb{R}^+$ be a signal with conditional density $f(\theta|q)$, which is twice continuously differentiable in $q$, and has full support for all $q$. Let $\bar{\theta} = \sup(\Theta)$ and let $f(\theta)$ be the marginal distribution of $\theta$. I assume that $f(\theta|q)$ is differentiable with respect to $\theta$, and that

---

6 A key assumption here is that the human capital investment cost is not fully tax deductible. This is certainly true for unobservable productivity improvements. In fact, the findings of Heckman, Lochner and Todd (2006b), and Heckman, Stixrud and Urzua (2006a) suggest a utility cost even for formal education. In Section 6, I consider an extension in which formal education is partially or fully tax deductible.

7 I discuss the possibility that information might differ across workers or firms in part D of Appendix A.
the monotone likelihood ratio property holds: i.e., \( \frac{\partial}{\partial \theta} \left( \frac{f(\theta|q_H)}{f(\theta|q_L)} \right) > 0 \) for all \( q_H > q_L \). Based on \( \theta \) and a prior \( \pi (q) \), each firm forms a posterior belief about the worker’s productivity.

Next, each of \(|J| \geq 2\) firms simultaneously offers a wage \( w_j \in \mathbb{R}_+ \) to the worker.\(^8\) The worker accepts her preferred offer, choosing firm \( j \in J \), and supplies labor \( l \in \mathbb{R}_+ \). Of her pre-tax income \( z \), the worker consumes \( c = z - T(z) \) where the function \( T \in \mathcal{T} \subseteq \mathcal{C} (\mathbb{R}_+, \mathbb{R}) \) is the tax system set by the social planner.\(^9\) In some parts of the paper, I restrict \( T(z) \) to be twice continuously differentiable.

**A. Worker and Firm Payoffs**

The worker receives utility \( u (z - T(z), l) - kx \), where: \( u_c > 0, u_l < 0, u_{cc} \leq 0 \) and \( u_{ll} < 0 \). I further assume that \( u_c \) is finite for all \( c > 0 \) and that \( \lim_{l \to \infty} u_l = -\infty \) and \( \lim_{l \to 0} u_l = 0 \). Firms are risk neutral and obtain benefit \( q \) per unit of supplied labor.

**B. Worker and Firm Strategies**

I focus on pure strategy equilibria.\(^10\) The worker’s strategy is a set of three functions – an investment decision, an acceptance rule and a labor supply decision. These can be written as: \( x : K \times \mathcal{T} \to \mathbb{R}_+ ; A : K \times \mathcal{T} \times \Theta \times \mathbb{R}_+^{|J|} \to J \); and \( L : K \times \mathcal{T} \times \Theta \times \mathbb{R}_+^{|J|} \to \mathbb{R}_+ \). Each employer’s strategy maps signals and tax systems to wage offers \( O_j : \Theta \times \mathcal{T} \to \mathbb{R}_+ \).

**C. Equilibrium Concept**

An equilibrium of the game induced by a given tax schedule is a Perfect Bayesian Equilibrium (PBE). This requires that firms’ beliefs are rationally formed using Bayes rule whenever it applies, and that all strategies satisfy sequential rationality.

**D. Optimal Firm and Worker Behavior**

Each firm chooses the wage \( w_j \) to maximize its expected profit \( \bar{P}_j \). Letting \( \Pr (A_j = 1|w_j) \) be the probability that the worker accepts firm \( j \)'s offer, its expected profit is:

\[
\bar{P}_{j,\theta} = E [P_j|\theta, \pi, w_j] = \Pr (A_j = 1|w_j) \times (E [q|\theta, \pi, A_j = 1] - w_j) \times l
\]

where \( l \) is the quantity of labor supplied by the worker.

Firms earn zero expected profit, and each worker’s wage \( w(\theta|\pi) \) is her expected marginal product \( E [q|\theta, \pi] \) given the signal \( \theta \) and the equilibrium productivity distribution.

---

\(^8\)This is without loss of generality because the marginal rate of substitution between consumption and labor does not depend on productivity. If it does, employers may be able to use menus to screen workers. Utility levels are still compressed, undermining incentives to invest (see Appendix A). Also in Appendix A, I discuss the implications of allowing for repeated interactions between workers and employers. Finally, note that employers and workers cannot write binding contracts on future outcomes at the time of investment.

\(^9\)I use \( \mathcal{C}(A, B) \) to denote the space of continuous functions mapping from \( A \) to \( B \).

\(^10\)In Appendix B, I discuss conditions that guarantee the existence of pure strategy equilibria.
Lemma 1. Fix a value of $\theta$ and assume $E[q|\theta, \pi]$ is strictly positive and finite given beliefs $\pi(q)$. In any pure-strategy equilibrium, all firms $j \in J$ earn zero expected profit, and the wage offered to each worker by each firm is her expected marginal product $E[q|\theta, \pi]$.

All technical proofs are presented in Appendix G.

After accepting a wage offer, the worker supplies labor $l(\theta|\pi, T)$ as follows.\(^{11}\)

\[
l(\theta|\pi, T) \in L^* = \arg\max_{l_j \in \mathbb{R}^+} u \left( w(\theta|\pi) \tilde{l} - T \left( w(\theta|\pi) \tilde{l} \right), \tilde{l} \right)
\]

In turn, this implies that her income is $z(\theta|\pi, T) = w(\theta|\pi) l(\theta|\pi, T)$. Knowing this, the worker can calculate her expected utility $v(\theta|\pi, T)$ for any signal realization.

\[
v(\theta|\pi, T) = u \left( z(\theta|\pi, T) - T \left( z(\theta|\pi, T) \right), \left( \frac{z(\theta|\pi, T)}{w(\theta|\pi)} \right) \right)
\]

Evaluating the expectation of $v(\theta|\pi, T)$ by integrating over $\theta$, investing $x$ leads to expected utility $V(Q(x)|\pi, T) = E_{\theta} [v(\theta|\pi, T) | Q(x)] - kx$. At the investment stage, a worker with cost $k$ takes the function $V(q|\pi, T)$ as given, and optimally invests $x(k|\pi, T)$, which solves problem 3. This yields productivity $q(k|\pi, T)$.

\[
x(k|\pi, T) \in X^* = \arg\max_{x \in \mathbb{R}^+} \int_{\Theta} v(\theta|\pi, T) f(\theta|Q(\tilde{x})) d\theta - k\tilde{x}
\]

In turn, these investment decisions collectively suffice to characterize the expected marginal product, and thus the wage, of an individual with signal realization $\theta$.

\[
w(\theta|\pi) = \frac{\int_{K} q(k|\pi, T) f(\theta|q(k|\pi, T)) dG(k)}{\int_{K} f(\theta|q(k|\pi, T)) dG(k)}
\]

The monotone likelihood ratio property ensures that the equilibrium wage is strictly increasing in $\theta$, and that $V(q|\pi, T)$ increases with $q$.

E. CHARACTERIZING AND SELECTING EQUILIBRIA

Equations 1, 3 and 4 describe a fixed point at which worker investment decisions and employer beliefs are consistent. Each employer has a correct prior belief $\pi(q)$, and rationally updates it upon observing a signal. Competition ensures that every firm offers the worker a wage equal to her expected marginal product. Combined with the signal distribution, this wage schedule then pins down the worker’s expected utility at each productivity level. Finally, the worker’s choices of productivity levels induce a productivity distribution that must coincide with every employer’s prior belief in equilibrium.

\(^{11}\)Throughout the paper, optimal choices of labor supply and investment will be unique.
Definition 1. An equilibrium is a set of worker and firm strategies such that: (i) the worker’s labor supply decision satisfies equation 1 for all signal realizations, $\theta$; (ii) worker investment decisions satisfy equation 3 for all cost draws, $k$; and (iii) the wage given signal $\theta$ is given by equation 4.

For any tax schedule $T$, there is a set of equilibria $E(T)$. I consider a selection of these equilibria, defined by choosing one equilibrium $E^\dagger(T) \in E(T)$ for each $T$.$^{12}$ The expected utility of a worker with investment cost $k$ is then defined as her expected utility given the tax schedule and this selection: $V(k, T) = V(k, E^\dagger(T), T)$. For example, one possibility is to assume that agents always coordinate on one of the social planner’s preferred equilibria. I assume that this is the case in my exposition of the results for non-linear taxation in Section 4. However, my approach is equally valid for other selections.

Note 1. The game here is described as one between a single worker and a set of firms, with the worker’s type $k$ drawn from $G(k)$. An alternative interpretation is that there is a continuum of workers whose investment costs have distribution $G(k)$ in the population. I adopt this more intuitive terminology throughout much of the paper.

F. The Social Planner

I now introduce the social planner who chooses a tax schedule $T$ to maximize social welfare $W(T)$. Welfare is defined as the average across types of the worker’s expected utility levels, $V(k, T)$, after they have been transformed by a social welfare function $W$.\(^{13}\)

$$\max_{T \in T} W(T) = \int_K W(V(k, T)) \, dG(k)$$

The social welfare function $W$ is assumed to be increasing, concave and differentiable. The choice of $T$ must satisfy two constraints. First, it can be a direct function only of realized income $z$. Second, enough tax revenue must be raised to cover an exogenously fixed revenue requirement, $R$. In some examples, I further restrict $T(z)$ to be linear.

The planner’s problem can be written as a choice of a tax system to maximize welfare, subject to the resource constraint, individual optimization and rational belief formation.

$$\max_{T \in T} W(T) = \int_K W(V(k, T)) \, dG(k)$$  \hspace{1cm} (5)

where:

$$V(k, T) = \int_\Theta (v(\theta|\pi, T) - kx(k, \pi, T)) f(\theta, q(k|\pi, T)) \, d\theta$$  \hspace{1cm} (6)

\(^{12}\)An alternative is to assume that the initial equilibrium is stable under a simple dynamic adjustment process. I define stability in Appendix B, and show how it ensures that investment responses to changes in $T$ can be written as the sum of an infinite sequence in much the same way as in Sachs et al. (2019).

\(^{13}\)I omit profits from welfare because they are zero in expectation. Allowing welfare to depend on realized utilities makes no qualitative difference, although the planner may then disrespect individual preferences.
In summary, the planner’s choice of a tax system $T$ alters the set of equilibria in the economy. Given a selection from this equilibrium correspondence – for example, the planner’s preferred equilibrium for each tax schedule – the planner maximizes welfare. Changes in the tax schedule shift the worker’s incentives to invest and her willingness to supply labor. Due to imperfect employer information, the worker’s investment decisions also affect equilibrium wages – an effect she ignores when she invests.\footnote{This can be thought of as a problem with inner and outer components à la Rothschild and Scheuer (2013), with rational belief formation serving as the consistency constraint. A difference is that Rothschild and Scheuer (2013) re-write the social planner’s problem as a direct choice over allocations.}

\section{A Simple Example with Linear Taxation}

I begin with an example in which income is taxed at a linear rate, $\tau$, with revenue redistributed as a lump sum.\footnote{For simplicity only, I also assume that the government’s revenue requirement, $R$, is zero.} A worker’s consumption is then a weighted average of her own income, $z$, and the mean income, $\bar{z}$: $c = (1 - \tau) z + \tau \bar{z}$. Workers have quasilinear isoelastic utility and that the production function for investment is also isoelastic.\footnote{I assume $\beta (1 + \varepsilon l) < 1$ so that the worker’s second-order conditions hold at the optimum.}

\begin{align*}
U &= c - l^{1 + \frac{1}{\varepsilon l}} (1 + 1/\varepsilon l) - kx \\
q &= x^\beta
\end{align*}

To ensure a tractable signal extraction problem for employers, I also make assumptions about the cost and signal distributions. First, the relationship between the signal $\theta$ and productivity $q$ is: $\ln(\theta) = \ln(q) + \ln(\xi)$, where $\ln(\xi) \sim N(0, \sigma^2_\xi)$. Second, investment costs $k$ are distributed log-normally: $k \sim LN(\ln(\mu_k - \sigma^2_k/2), \sigma^2_k)$.

\subsection{Equilibrium}

Given a tax rate $\tau$, there is an equilibrium in which productivity and income are log-normally distributed.\footnote{Appendix A Part F considers linear taxation more generally without parametric assumptions.} In this equilibrium, a worker’s wage is a geometric average of her own productivity $q$, average productivity $\mu_q$, and idiosyncratic noise. The weight on a worker’s own productivity (via the signal) is the share of the variance of the signal that
comes from productivity rather than noise, \( s = \sigma_q^2 / (\sigma_q^2 + \sigma_\xi^2) \). Intuitively, the signal is only useful to employers if variation in it reflects differences in productivity.

**Proposition 1.** For any fixed tax rate \( \tau \), there exists an equilibrium in which productivity and income are both log-normally distributed.

\[
\ln q \sim \mathcal{N}\left( \ln \mu_q - \frac{\sigma_q^2}{2}, \sigma_q^2 \right)
\]

A worker’s wage is \( w = q^s \mu_q^{1-s} \xi^s \) where \( s = \frac{\sigma_q^2}{\sigma_q^2 + \sigma_\xi^2} \in (0, 1) \).

The weight on a worker’s own productivity is a measure of the wedge between the private and social returns to investment. If a worker of a given cost type were to unilaterally increase her productivity by one percent, her expected wage would increase by \( s < 1 \) percent. If the signal is noisy (\( \sigma_\xi^2 \) large), then \( s \) is close to zero; the signal is of little practical use to employers in this case, and they largely ignore it when setting a worker’s wage. There is thus little private return to investment. Alternatively, if \( \sigma_\xi^2 \) is small, then \( s \) is close to one, and the private return to investment is close to the social return.

The simplicity of this example stems from the fact that the elasticities of investment and income with respect the retention rate, \( 1 - \tau \), are constant. Specifically, they are independent of the precision of the signal. On one hand, more noise in the signal causes employers to pay less attention to it, flattening the relationship between a worker’s productivity and her log wage. But as employers place more weight on average productivity, each worker’s investment increasingly raises the wages of other workers as well. The two effects cancel out, leaving the elasticities unaffected by the quality of the signal.

**Lemma 2.** Assume that the log-normal equilibrium from Proposition 1 is played. The elasticities of productivity (\( \varepsilon_q \)) and income (\( \varepsilon_z \)) with respect to the retention rate \( 1 - \tau \) are:

\[
\varepsilon_q = \frac{\beta (1 + \varepsilon_l)}{1 - \beta (1 + \varepsilon_l)} \quad \quad \varepsilon_z = \frac{\varepsilon_l + \beta (1 + \varepsilon_l)}{1 - \beta (1 + \varepsilon_l)}
\]

**B. OPTIMAL TAXATION**

Building on Lemma 2, Proposition 2 provides a formula for the optimal linear tax, \( \tau^* \). In equation 11, \( \psi_k = W'(\overline{v}(k, \tau)) \) is the marginal social welfare weight placed on workers with cost \( k \), and \( \overline{\psi} \) is the average welfare weight. The average income for individuals with cost \( k \) is \( \overline{z}_k \), and \( \overline{z} \) is the average income across workers of all types.

**Proposition 2.** Assume that the log-normal equilibrium described in Proposition 1 is played. The first-order condition for the optimal linear tax \( \tau^* \) is:
\[
\frac{\tau^*}{1 - \tau^*} = \frac{1 - \gamma}{\varepsilon_z} - \frac{\gamma (1 - s) \varepsilon_q}{\varepsilon_z}
\] (11)

where: \(\gamma = E_k \left\{ \frac{\psi_k \bar{z}_k}{\psi \bar{z}} \right\} \geq 0\).

Equation 11 is closely related to the optimal tax formula in the standard setting with perfect employer information. The first term captures the usual trade-off between redistribution and distortion. The second term is new, and captures the intuition that workers who become more productive impose a positive externality on others by making employers more optimistic, raising the wage paid for any given signal realization.

The formula in Proposition 2 can be derived by combining the three effects of slightly raising the tax rate, the sum of which must be zero at the optimal tax rate. First, there is a mechanical effect (ME). This is the welfare gain from taking resources from individuals in proportion to their incomes, and then redistributing it as a lump sum.

\[
ME = \bar{\psi} \bar{z} - E_k (\bar{\psi_k} \bar{z}_k)
\]

This redistribution raises social welfare to the extent that workers with higher income have lower welfare weight: \(E_k (\bar{\psi_k} \bar{z}_k) < \bar{\psi} \bar{z}\). If welfare weights decline rapidly with income, \(\gamma\) is close to zero and \(\tau^*\) is high. Conversely, a social planner with only a weak preference for redistribution has \(\gamma\) close to one, which implies a low value of \(\tau^*\).

The second traditional effect of taxation is the fiscal externality (FE), which captures the impact of changes in labor supply and investment decisions on the government budget.

\[
FE = -\tau \bar{\psi} \varepsilon_z \frac{\bar{z}}{1 - \tau}
\]

When workers re-optimize in response to a change in \(\tau\), the effect of this on their own welfare is second-order (by the envelope theorem). However, there is a first-order effect on government revenue, which is returned to workers. In classic income taxation models, the fiscal externality is a sufficient statistic for the cost of taxation (Feldstein 1999).

With imperfect employer information, there is a new effect which I call the belief externality (BE). When workers increase their investment, they do not take into account the fact that employers become more optimistic as average productivity rises, raising the wage paid given each signal realization. This constitutes a second externality.

\[
BE = -E_k (\psi_k \bar{z}_k) (1 - s) \varepsilon_q
\]

As equation 11 shows, this new effect lowers the optimal tax rate. Its impact rises with the wedge between private and social returns, \(1 - s\), which is large if employers’ information
Figure 2: Welfare Impacts of a Lower Tax Rate

Figure notes. This figure shows the effects of a small reduction in \( \tau \) on utility at each initial productivity level in the example, calibrated to match the United States wage distribution (see Appendix I). Workers capture 75\% of the returns to their investments \((s = 0.75)\) in this example. The impacts in are in dollars of after-tax income per percentage point of the tax rate reduction, but are scaled by the productivity density so that the area under each curve is proportional to the average impact.

about workers is imprecise. It also scales with \( \varepsilon_q \): if productivity did not respond to taxation, lowering taxes would be poorly targeted to correct an externality from human capital investment.\(^{18}\) Finally, the welfare impact rises with \( E_k (\psi_k z_k) \), because higher-income individuals (who supply more labor) are affected most by changes in their wage.

C. Graphical Demonstration

Figure 2 shows the effect of a small reduction in the linear tax rate. The effects are weighted by the density of the productivity distribution so that the area between each curve and zero is the average utility impact. Since the tax rate has been reduced, there is a mechanical transfer of utility from low- to high-productivity workers. Second, there is a positive fiscal externality, as incomes rise and the government collects more revenue. Finally, there is a positive belief externality: as employers become more optimistic, they pay workers a higher wage given any signal realization.

D. Special Cases

It is instructive to consider three special cases of the optimal tax formula. First, if employers perfectly observe productivity \((s = 1)\), equation 11 collapses to the standard case.

\(^{18}\)This highlights a difference from Mirrlees (1971), where “labor supply” is equivalent to other kinds of effort that produce income. Here, human capital investment produces a spillover but labor supply does not.
While it is critical that $\varepsilon_z$ incorporates the long-run response of human capital in any quantitative application, this equation is otherwise the same as that which arises in a model with fixed productivity types and perfect employer information.

In general, however, there is an efficiency motive to intervene. This is clearly reflected by the formula that arises when the planner has no redistributive motive (i.e., $\psi_k = 1 \forall k$).

$$
\left. \frac{\tau^*}{1 - \tau^*} \right|_{s=1} = \frac{1 - \gamma}{\varepsilon_z}
$$

(12)

In this case, the planner simply aims to align private and social returns. Finally, this can be contrasted with a Rawlsian planner, who cares only about the highest-cost worker. The Rawlsian tax rate, $\left. \frac{\tau}{1 - \tau} \right|_{r} = \frac{1}{\varepsilon_z}$, maximizes government revenue; it is unchanged by the belief externality because the highest-cost worker is unaffected in this example.

**E. Optimal Tax Rate as a Function of the Parameters**

The belief externality always lowers the optimal tax rate, but the size of the adjustment changes with the parameters. Figure 3 quantifies the impact of the externality by comparing the true optimal tax rate to the rate implied by the traditional optimal tax formula. Across the panels, I vary the four key objects in equation 11: the size of the externality ($1 - s$); the elasticity of taxable income ($\varepsilon_z$); the ratio of the income and wage elasticities ($\varepsilon_q / \varepsilon_z$); and the covariance between social welfare weights and income ($\gamma$).

The top panel varies the magnitude of the externality and the social welfare criterion. If the planner places more weight on individuals with higher incomes ($\gamma \uparrow$) or the externality gets larger ($s \downarrow$), the ratio $\tau / (1 - \tau)$ falls linearly. However, the impact on the level of the tax rate ($\tau$) is non-linear: the marginal impacts on $\tau$ become larger for higher levels of $\gamma$ because the traditional tax formula already implies lower tax rates. In the bottom panel, we see that the ratio of the wage elasticity to the income elasticity is a critical determinant of the impact of the belief externality. By contrast, the elasticity of taxable income is much less important. These lessons regarding the wage and income elasticities are reinforced by the range of more-detailed quantitative exercises I consider in Section 5.

4 Non-linear Taxation

I now relax the restrictive assumptions of Section 3, and derive a necessary condition for optimal non-linear taxation by studying a small perturbation to the tax schedule. Specifically, I consider raising the marginal tax by $d\tau$ over a small range of incomes between $z$ and $z + dz$, where $d\tau$ is second-order compared to $dz$. This is accompanied by a change in
Figure 3: Linear Tax Rate Adjustment due to Learning Externality

(a) Adjustment as Social Welfare Function and the Externality Vary

(b) Adjustment as the Income and Wage Elasticities Vary

Figure notes. This figure plots the difference between the optimal tax rate in the example with linear taxation (equation 11) and the tax rate implied by the standard optimal tax formula. Panel (a) holds the wage elasticity ($\epsilon_q$) and the income elasticity ($\epsilon_z$) constant at 0.75 and 1 respectively. It then shows the tax adjustment made for different social welfare functions – captured by the covariance between social welfare weights and income ($\gamma$) – and different sizes of the externality ($1 - s$). Panel (b) fixes $\gamma = 0.8$ and $s = 0.75$, then varies the income elasticity and the ratio of the wage elasticity to the income elasticity.
Figure notes. This figure shows the effect of a stylized perturbation. The hypothetical marginal tax change applies in the shaded region, lowering the slope of the relationship between after-tax and before-tax income.

the intercept of the tax schedule – a uniform increase in the consumption of all workers – to ensure that the resource constraint still holds with equality.¹⁹

An example of such an experiment is shown in Figure 4. Studying the effects of this perturbation leads to a tax formula that bears a conceptually close relationship to the standard one that arises when workers simply receive their marginal product (Mirrlees 1971, Diamond 1998, Saez 2001). As in the example above, there are three effects: a mechanical effect (ME), a fiscal externality (FE) and – new to this model – a belief externality (BE).

A. Regularity Assumptions

In deriving a condition that characterizes the optimal tax, I take a continuously differentiable tax schedule \( T \) and the social planner’s preferred equilibrium given that tax schedule, \( E^* (T) \).²⁰ I adopt regularity assumptions, which jointly ensure that a worker’s income responds smoothly to small changes in her wage or the tax schedule around this initial point, and that there is – generically, for an arbitrarily chosen tax schedule – a locally unique Fréchet differentiable function mapping tax schedules to investments.²¹

¹⁹My exposition parallels Saez (2001) but little changes with general perturbations (see Gerritsen 2016). Requiring \( d\tau \) to be small abstracts from bunching and gaps from introducing a kink in the tax schedule. Note that the perturbation incorporates the tax revenue that is rebated when marginal tax rates are raised, unlike Saez (2001). The two approaches are equivalent if the tax system is set optimally.

²⁰Although I assume for concreteness that the planner can implement her preferred equilibrium, my approach is equally valid for any other locally continuous selection of equilibria.

²¹I discuss the existence of a locally unique selection of equilibria in Appendix B. Appendix C discusses why the planner may in some cases choose to locate at a singularity where these conditions break down.
First, I make the standard single crossing assumption, which is that the marginal rate of substitution between income and consumption is decreasing in the wage (Assumption 1). Second, I assume that individuals’ second-order conditions for labor supply hold strictly (Assumption 2). As discussed by Saez (2001), this requires that 
\[ 1 - T'(z) + \varepsilon_c^z z T''(z) > 0, \]
where \( \varepsilon_c^z \) is the compensated elasticity of taxable income with respect to her wage. Assumption 2 can be viewed as a restriction on the curvature of the tax schedule. It always holds in my simulations, and must hold if \( T''(z) \geq 0 \).

**Assumption 1 (Single Crossing).** *The marginal rate of substitution between income and consumption, \(-\frac{u_l(c, z)}{w u_c(c, z)}\), is decreasing in \( w \).*

**Assumption 2 (Labor Supply SOC).** *The second derivative of the tax schedule \( T''(z) \) is bounded strictly below by \(-\frac{1}{\varepsilon_c^z} [1 - T'(z)]\).*

Third, I assume that investment returns are strictly concave, so that workers’ second-order conditions for investment hold strictly (Assumption 3). This is a joint restriction on the tax schedule, cost distribution \( G(k) \) and investment technology \( Q(x) \). For any income, wage and productivity distributions, and any tax schedule, there exist cost distributions and investment technologies such that condition 13 holds. It can also be relaxed, with the key requirement being that workers are not indifferent between two decisions. With finitely many cost types, this is satisfied generically; and with a continuum of cost types, the analysis is unchanged if it is violated for countably many cost types.

**Assumption 3 (Investment SOC).** *Investment returns are strictly concave for all \( x \).*

\[
-\frac{Q''(x)}{Q'(x)^2} > \frac{\int_{\Theta} v(\theta|\pi, T) \frac{\partial^2 f(\theta|q)}{\partial q^2} \bigg|_{q=Q(x)} d\theta}{\int_{\Theta} v(\theta|\pi, T) \frac{\partial f(\theta|q)}{\partial q} \bigg|_{q=Q(x)} d\theta} \]

(13)

**B. Mechanical Effect**

Subject to these regularity assumptions, there are three effects of the proposed perturbation. I begin with the mechanical effect (ME) of taxation. Raising the marginal tax at income \( z \) collects revenue from workers with income greater than \( z \) and redistributes it equally to all workers by raising the intercept of the tax schedule.

Assumptions 1 and 2 ensure that income is strictly increasing in \( \theta \). As a result, \( z(\theta|\pi, T) \) can be inverted to obtain \( \theta(z|\pi, T) \). Defining \( G(k|\theta) \) as the distribution of \( k \) conditional on \( \theta \), and letting \( \psi(k) = W'(\nabla(k, T)) \), the mechanical gain in welfare is \( d\tau dz \times \):
\[
\int_\Theta u_c(\theta) \int_K \psi(k)dG(k|\theta)\,d\theta \times \int_{\theta(z|\pi,T)}^{\theta} f(\theta)\,d\theta - \int_{\theta(z|\pi,T)}^{\theta} u_c(\theta) \int_K \psi(k)dG(k|\theta)\,f(\theta)\,d\theta
\]

Value of transfer to average worker

Loss due to transfer from high income workers

To simplify this expression, let \( H(z) = \int_0^z h(v)\,dv \) be the CDF of income. Secondly, let \( \psi_z(z) \) be the normalized marginal social welfare weight of a worker with income \( z \).

\[
\psi_z(z) = \frac{u_c(\theta(z|\pi,T)) \int_K \psi(k)dG(k|\theta(z|\pi,T))}{\int_\Theta u_c(\theta) \int_K \psi(k)dG(k|\theta)\,f(\theta)\,d\theta}
\]

Finally, define \( \Psi(z) = \int_0^z \psi_z(v) h(v)\,dv \) as the cumulative welfare weight of workers with income less than \( z \). Using these definitions, the mechanical gain can be written as:

\[
\text{ME}(z) = d\tau dz \times \{ \Psi(z) - H(z) \}. \tag{14}
\]

Since \( \psi_z(z) \) is decreasing in \( z \), the welfare weight below any finite level of income is higher than the population weight.\(^{23}\) This in turn implies that \( \text{ME}(z) > 0 \). Intuitively, transferring income from relatively rich individuals to the broader population of workers mechanically raises social welfare for a planner with a taste for redistribution.

C. FISCAL EXTERNALITY

The second effect of the perturbation is the fiscal externality, which arises because workers ignore the effects of their decisions on government revenue. Not only do workers respond directly, but each response alters the investment incentives of other workers by changing the equilibrium wage schedule. The fiscal externality is thus governed by the evolution of a fixed point at which workers’ investment decisions are optimal given employers’ beliefs, and employers’ beliefs are rational given workers’ investment decisions.

The total fiscal externality is given by equation 15, and is comprised of two effects. First, there are changes in the marginal density of the signal; these arise directly in response to changes in workers’ investments. Second, there is a change in the level of income corresponding to each signal realization, \( z(\theta|\pi,T) \). The change in \( z(\theta|\pi,T) \) captures two types of reaction: (i) direct responses of labor supply to the policy change; and (ii) changes in wages and labor supply due to shifts in employer beliefs.

\[
\text{FE}(z) = -d\tau dz \int_\Theta \left\{ T'(z(\theta|\pi,T)) \left( \frac{dz(\theta|\pi,T)}{dT'(z(\theta|\pi,T))} \right) f(\theta) + T(z(\theta|\pi,T)) \frac{df(\theta)}{dT'(z(\theta|\pi,T))} \right\} d\theta
\]

Response of income given \( \theta \) realization

Direct effect of investment

\(^{23}\)Since \( \psi(k) \) is increasing in \( k \), the assumptions on \( f(\theta|q) \) guarantee that \( \int_K \psi(k)dG(k|\theta) \) is decreasing in \( \theta \). Finally, \( u_c(\theta) \) is weakly decreasing and \( z(\theta|\pi,T) \) strictly increasing, so \( \psi_z(z) \) is strictly decreasing.
The derivatives in equation 15 are causal responses to this perturbation to the tax schedule, which are not directly related to properties of the utility function. In fact, they are the result of readjustment of equilibrium actions by all workers and firms. Appendix B shows how these equilibrium responses can be rewritten as infinite series in terms of fundamentals, in an analogous way to the general equilibrium analysis of Sachs et al. (2019).

D. Belief Externality

The final effect of the perturbation is new to this model. When individuals re-optimize their investment decisions, they disregard the effect of this on the equilibrium wage paid for a given signal realization, \( w(\theta|\pi) \). Taking any signal realization \( \tilde{\theta} \), this wage externality is comprised of two components, corresponding to the two effects of a worker’s investment: an increase in productivity, and a shift in her signal distribution.

\[
\frac{dw(\tilde{\theta}|\pi)}{d[1-T'(z)]} f(\tilde{\theta}) = \int_K \left( \frac{dq(k|\pi, T)}{d(1-T'(z))} \right) \left[ f(\tilde{\theta})q(k|\pi, T) \right] \int_{\tilde{\theta}}^{K} \left( \frac{\partial f(\tilde{\theta}|q)}{\partial q} \right|_{q=q(k|\pi, T)} \right) dG(k)
\]

The first component of equation 16 is the productivity effect. A worker who invests more shifts employers’ beliefs upward, and causes the wage paid to individuals with signal \( \tilde{\theta} \) to rise despite their own investment and productivity being unchanged.

The second component is the rent transfer effect, which is negative. As shown in Figure 5, if worker \( i \) invests more, she becomes more likely to send high signals where her true productivity is lower than the expectation given that signal realization (\( q_i < E(q|\tilde{\theta}, \pi) \)). This lowers the expectation of productivity given those high signals, and thus lowers the wages of other workers who send them. At the same time, she is less likely to send low signals where her productivity is higher than the expected productivity given those low signals. Thus, since \( q_i > E(q|\tilde{\theta}, \pi) \), that expectation falls as her relatively high productivity contributes less to it than before. In turn, this lowers the wages of other workers who send such low signals in equilibrium. The intuition for this effect is related to job market signaling (Spence 1973): as a worker sends more high signals and fewer low signals, she becomes more likely to be pooled with others who are more productive than herself (which is bad for them), and less likely to be pooled with those who are less productive (which would have been good for them).

The productivity and rent transfer effects differ in both sign and incidence. As workers re-optimize, the productivity effect raises the equilibrium wages of workers whose
Figure notes. This figure shows the stylized impact of a change in a worker’s productivity from $q_1$ to $q_2$ on her conditional signal distribution, $f(\tilde{\theta}|q)$. The rent transfer effect scales with the change in $f(\tilde{\theta}|q)$, which is large when the slope of $f(\tilde{\theta}|q)$ is steep. By contrast, the productivity effect scales with the level of $f(\tilde{\theta}|q)$.

signal distributions overlap most with those who increased their productivity. This gain is proportional to the level of the conditional signal distribution, $f(\tilde{\theta}|q)$. In contrast, the rent transfer effect reduces the wages of workers who send signals in regions where $f(\tilde{\theta}|q)$ changes the most. As Figure 6 suggests, this is a different set of workers: in terms of their productivity levels, they are likely to be less similar to those who changed their investment decisions than are the beneficiaries of the productivity effect.

The importance of these differences in incidence are apparent in Figure 7, which starts from the linear tax example in Section 3 and shows the simulated effects on wages of a reduction in the marginal tax rate on income between $60,000$ and $61,000$. When the marginal tax rate falls and productivity rises, panel (a) shows that there is a large positive externality on workers around the epicenter of the productivity response, but also a negative effect on workers who are further way. If the overall externality is larger as in panel (b), the effects are dispersed more widely, and the positive productivity effect outweighs the negative rent transfer effect over nearly all of the distribution. As the example in Section 3 shows, the net externality can in fact positive everywhere. But it is also important to note that in any case in which some people are negatively affected, there exist extreme examples of social welfare functions such that welfare is reduced.

The total belief externality is calculated as follows. The effect on consumption is obtained by scaling the wage effect by labor supply, $l(\tilde{\theta}|\pi, T)$, and the retention rate.
**Figure 6: Response to a Marginal Tax Rate Change**

(a) Small Belief Externality ($s = 0.95$)

(b) Larger Belief Externality ($s = 0.75$)

*Figure notes.* These figures show the effects of a reduction in the marginal tax rate on income between $60,000 and $61,000. The baseline economy is the linear taxation example, calibrated to the United States. The wage and income distributions are the same in both panels. The effect at each productivity level is scaled by the density so that the area under each curve is proportional to the average wage change due to that component. The dotted line shows the direct impact of due to the change in each agent's investment decision, holding beliefs constant. The solid line shows the total wage impact. Finally, the shaded area is the externality.
1 − \(T'(z)\). Next, the effect on social welfare is obtained by multiplying by the welfare weight, \(\psi_z\). The total impact is then calculated by integrating over the signal distribution.

\[
BE(z) = -dT dz \left\{ \int_\Theta \psi_z(\tilde{\theta}|\pi, T) \left[ 1 - T'(z(\tilde{\theta}|\pi, T)) \right] l(\tilde{\theta}|\pi, T) \left( \frac{d\psi(\tilde{\theta}|\pi)}{d[1 - T'(z)]} \right) f(\tilde{\theta}) \right\}
\]

(17)

E. “U”-SHAPED TAX SCHEDULES AND THE IMPORTANCE OF INCIDENCE

An intuitive special case arises when the tax rate is initially flat, there is no redistributive motive for taxation, and labor supply is perfectly inelastic. In this case, the incidence of a wage change is irrelevant. The belief externality is thus proportional to the difference between the average productivity increase (which is the social benefit of investment), and the average private gain from investment. In other words, it is the component of the average wage gain that is not internalized by marginal investors.

\[-BE(z) \propto \frac{d\tilde{\theta}}{d(1 - T'(z))} \left\{ \int_K \left[ \int_\Theta \left( \frac{df(\theta|q)}{d(1 - T'(z))} \right|_{q=q(k|\pi, T)} \right) w(\theta|\pi) d\theta \right\} w(\theta|\pi) d\theta \]

The private return to investment comes from sending better signal realizations to employers, and depends on the quality of the signal. The social benefit is independent of it.

Without these strong assumptions on welfare weights, labor supplies and initial tax rates, equation 17 shows that each wage change is re-weighted in a way that is important in driving the shape of the optimal tax schedule. It is more important if it affects a worker whose labor supply is high, but who receives significant welfare weight. This means that the externality has a larger impact on welfare if it affects workers with intermediate incomes. In turn, this contributes to a “U”-shaped optimal tax schedule. Finally, the weights are proportional to the retention rate, \(1 - T'\). This amplifies the effects of other forces in the model, compounding the “U” shape that already arises from the trade-off between mechanical redistribution and the fiscal externality (see Diamond 1998).

F. A NECESSARY CONDITION FOR OPTIMALITY

Bringing everything together, this perturbation leads to three effects: \(ME(z), FE(z)\) and \(BE(z)\). Figure 7 shows these effects graphically. Just as in the example in Section 3, the mechanical effect from a reduction in the marginal tax rate transfers utility from workers with low productivity to those with high productivity, and the fiscal externality raises the utility of all workers. For most workers, the belief externality is also positive.

If \(T\) is optimal, the three effects must sum to zero for all \(z\). Otherwise, there exists a change to the tax schedule that raises welfare. This is summarized in Proposition 3.
Figure notes. This figure shows the effects on utility of a rise in the marginal tax rate on income between $60,000 and $61,000. The baseline economy is the linear taxation example, calibrated to achieve $s = 0.75$ in equilibrium and match the United States wage distribution. The effect at each productivity level is scaled by the productivity density so that the area under each curve is proportional to the aggregate impact. The gray-shaded bar shows the wage range that is directly affected by this perturbation.

Proposition 3. Consider an arbitrarily small perturbation that raises the marginal tax rate by $d\tau$ between income $z$ and $z + dz$, with $d\tau$ second order compared to $dz$. The effect on social welfare is:

$$
\text{ME}(z) + \text{FE}(z) - d\tau dz \int_Z \tilde{z} \psi_z(\tilde{z}) \left( \frac{1 - T'(\tilde{z})}{1 - T'(z)} \right) \varepsilon_{\pi}^{\pi(\tilde{z}),1-T'(z)}dH(\tilde{z})
$$

where:

$$
\varepsilon_{\pi}^{\pi(\tilde{z}),1-T'(z)} = \frac{dw(\theta(\tilde{z}) | \pi)}{d[1 - T'(z)]} \times \frac{1 - T'(z)}{w(\theta(\tilde{z}) | \pi)}.
$$

Except at a discontinuity, $\text{ME}(z) + \text{FE}(z) + \text{BE}(z) = 0$ for all $z$ if $T$ is optimal.

If expression 18 is zero, there is no first-order gain from perturbing the tax schedule and moving to an equilibrium near the status quo. This is similar to the first-order condition that characterizes optimal taxation in Mirrlees (1971), but it does not have as simple a representation.\textsuperscript{25} The externality correction cannot be written as an additive adjustment to the standard formula as in Sandmo (1975) and Kopczuk (2003). The reason is that the decisions that generate the externality cannot be directly targeted. Rather, as the income tax changes, individuals throughout the productivity distribution respond.

\textsuperscript{25} Although expression 18 cannot be written in terms of sufficient statistics, I show in Appendix E that 60 percent of the gain from optimal taxation can be obtained using a simple approximation.
A limitation to Proposition 3 is that expression 18 must be zero at an optimum around which there exists a continuous selection of equilibria, but not at a discontinuity if one exists. Assumptions 1 to 3 ensure continuity for a generic tax schedule, but I show in Appendix C how to construct examples in which the planner chooses to locate at a point at which strategies and welfare jump discontinuously in response to a perturbation in some direction. At such a point, the first-order approach breaks down, and the planner would optimally locate the economy on the side of the discontinuity with higher welfare. This does not occur at any point in the quantitative work below or in the example in Section 3. Neither does it affect the use of expression 18 to search for welfare gains in practice.

5 Quantitative Analysis

My next step is to use empirical evidence to assess the size of the belief externality. Since employers gradually learn the productivity of their workers, the statistic required to calibrate the model is the share of the present-discounted return to marginal human capital investment that a worker captures. As I show below, this is determined by the speed at which employers learn about worker productivity.

To connect the model to dynamic evidence, let \( q \) be the worker’s human capital and assume human capital investment occurs before entry into the labor market.\(^{26}\) However, her marginal product, \( \text{MP}_t(q) \) may depend on experience, \( t \). In each period, let employers see a different signal \( \theta_t \in \Theta_t \), which may become arbitrarily precise over time. The worker is still paid her expected marginal product, \( E(\text{MP}_t(q)|\theta_t, \pi) \), and her discount factor is \( \delta \).

Initially, assume utility is quasilinear, taxation is linear and labor supply is perfectly inelastic. Then the fraction of the social return to increasing \( q \) that the worker captures is:

\[
\begin{align*}
\sum_{t=0}^{T} \delta^t \int_{\Theta_t} E(\text{MP}_t(q)|\theta_t, \pi) \frac{\partial f_t(\theta_t|q)}{\partial q} d\theta_t \\
\sum_{t=0}^{T} \delta^t \frac{\partial \text{MP}_t(q)}{\partial q} 
\end{align*}
\]

where \( f_t(\theta_t|q) \) is the conditional distribution of the period \( t \) signal.

The expression on the right of equation 19 is simply the present-discounted private return to higher productivity divided by the present-discounted social return. It takes into account the fact that employers gradually learn a worker’s productivity, so that the worker is fully remunerated for her productivity later in life. Nonetheless, at earlier stages in her career – which are more important due to discounting – the discounted private return is lower than the discounted social return. Below, I show how to calculate this statistic based

\(^{26}\)Appendix A discusses human capital investments over a worker’s career, and repeated interaction between workers and firms. Extending the analysis to these cases is complex without strong assumptions, but has implications for age-dependent or dynamic taxation. This is an important avenue for future research.
on the available empirical evidence. In addition, all my results take into account the fact that workers’ tax rates, labor supplies and welfare weights change with their wage.  

A. EMPIRICAL EVIDENCE ON EMPLOYER LEARNING

The dominant approach to measuring the speed of employer learning was pioneered by Farber and Gibbons (1996) and Altonji and Pierret (2001). They posit that the econometrician observes a productivity correlate that employers do not see, or which they are not legally allowed to use. This is usually a score on the Armed Forces Qualification Test (AFQT) from before the worker entered the labor market. Using workers’ AFQT scores and wages, these studies involve estimation of a version of equation 20, often using data from the National Longitudinal Survey of Youth (NLSY).

\[
\ln w = \alpha_0 + \rho_0 \text{AFQT} + \rho_1 \text{AFQT} \times \text{Experience} \\
+ \gamma_0 \text{Education} + \gamma_1 \text{Education} \times \text{Experience} \\
+ \lambda_0 \text{Experience} + \lambda_1 \text{Experience}^2 + \lambda_2 \text{Experience}^3 + X'\beta + \varepsilon
\] (20)

The typical finding is that \(\rho_1\) is strictly positive. This is interpreted as evidence that employers do not fully reward workers for their productivity at first, but that the reward increases over time. A simultaneous finding that \(\gamma_1 < 0\) further supports the hypothesis that learning is occurring: employers initially use education to gauge productivity, but they obtain more direct information as time progresses. As they observe workers and learn more, they rely less on pre-existing productivity correlates such as education.

Building on this approach, Lange (2007) shows how to quantify the speed at which employers learn. To do so, he flexibly estimates – at each level of experience – the return to a higher AFQT score, and the return to schooling. Conditional on schooling, the return to a higher AFQT is zero initially, but increases with experience. Conversely, the return to schooling declines with experience. The non-parametric results are closely approximated by a model in which employers learn at a constant rate, \(K\), which measures the precision of information received in each period relative to the information they have at the start of a worker’s career. Lange refers to \(K\) as the speed of employer learning.

In each period, Lange’s (2007) empirical model implies that a worker’s expected productivity is a weighted average of the employer’s initial belief and her true productivity, with this weight increasing over time. Specifically, after \(e\) years of experience, the weight on a worker’s true productivity is implied directly by \(K\).

\[^{27}\text{Note that a multi-period model would more fully account for these types of adjustments over the life-cycle, but the difference would be minor. In the extension shown in Figure I3, I also allow for risk aversion.}\]

\[^{28}\text{Human resources managers harbor concerns that the unjustified use of general ability tests could lead to charges of discrimination, which may explain why they are not widely used as hiring tools (Lange 2007). Furthermore, the predictive power of tests like the AFQT has only been established recently.}\]
Weight on True Productivity = \frac{eK}{1 + (e - 1)K} \tag{21}

Column 1 of Table 1 shows several estimates of the speed of employer learning. The first two rows contain estimates from Lange (2007): one based on how quickly the return to a higher AFQT increases \((K = 0.229)\), and another \((K = 0.259)\) that combines this with information about the decline in the return to schooling with experience. The last two rows show Aryal, Bhuller and Lange’s (2020) estimates for Norway: the first is based on a similar methodology to Lange (2007), while the second uses a different strategy that harnesses instrumental variable estimates of the return to schooling.\textsuperscript{29}

\textit{Table notes.} This table shows estimates of the fraction of the present discounted social return to higher productivity that is captured by workers. Each cell is calculated using a different discount rate and speed of employer learning. In all cases, the lifecycle wage profile is taken from Lagakos, Moll, Porzio, Qian and Schoellman’s (2018) estimates for the United States. See Appendix H for further details.

Each estimate of the speed of learning implies a wedge between the present discounted private and social returns to productivity – i.e., \(s\) in equation 19. While I defer detailed discussion of these calculations to Appendix H, there are two key considerations to incorporate. First, I take into account variation in average wage rates over the lifecycle using estimates from Lagakos et al. (2018); this is important because any given percentage gap between private and social returns has a larger dollar impact later in life when wages are higher. Second, pushing in the opposite direction, future wage impacts are discounted. As Appendix H Figure H1 shows, the net effect is that the gap between private and social returns over the first decade of a worker’s career is most important.

The results of these calculations are shown in Table 1. Since all the estimates imply a meaningful delay before a worker is fully rewarded for her productivity, they also imply a substantial wedge between the present discounted private and social returns to improving it. In other words, the results imply that the belief externality is large on average. Nonetheless, differences in the discount factor and rate of learning are important. For example, given a discount factor of 0.95, the fraction of the social return to higher produc-

\textsuperscript{29}Pastorino (2019) and Camargo, Lange and Pastorino (2021) find slower learning, but do not provide comparable quantitative estimates. Slower learning would imply a larger externality, and an even larger adjustment to optimal income taxes than is shown in my quantitative work below.
tivity captured by workers ranges from 73% to 88%.

Kahn and Lange (2014) find similar results using a very different method. They start by acknowledging a limitation of Lange’s (2007) approach: if productivity evolves heterogeneously over the lifecycle, this could be part of the explanation for why the weight on AFQT increases with experience. Recognizing this, they aim to isolate the role of employer learning by building on a key insight specific to belief updating: since it is backward-looking, it predicts that innovations in pay correlate more with past than future innovations in performance, because firms rely on past information to set wages.

Using a structural model and a panel dataset with information about both wages and performance reviews, Kahn and Lange (2014) find that workers capture between 60 and 90 percent of the present-discounted social return to an innovation in their productivity during the first 15 years of their careers – although they capture a smaller fraction in the later years. This implies that 10 to 40 percent of the social return accrues to others, which is consistent with the range of calculations in Table 1.

Many other studies suggest that employers imperfectly observe worker productivity. MacLeod, Riehl, Saavedra and Urquiola (2017) study the introduction of college exit exams in Colombia. Consistent with learning, they show that when more information about productivity becomes available, wages increasingly reflect individual ability rather than college reputation. There is also evidence from online marketplaces that information is imperfect (Stanton and Thomas 2016), and that more information improves outcomes (Pallais 2014, Pallais and Sands 2016). Likewise, Abel, Burger and Piraino (2020) show that reference letters are a valuable but under-used source of information about workers.

Finally, numerous studies uncover evidence of statistical discrimination, which is itself evidence of imperfect information. For example, Blair and Chung (2018) find that occupational licensing reduces reliance on race and gender; and drug testing is shown by Wozniak (2015) to positively impact black employment. Conversely, Agan and Starr (2018) and Doleac and Hansen (2016) show that racial discrimination increases when employers are banned from asking about criminal histories; and Shoag and Clifford (2016) find that banning the use of credit checks leads to relative increases in employment in low credit score census tracts, and more demand for other information about productivity.

B. HETEROGENEITY IN EMPLOYER LEARNING

The estimates in Table 1 provide guidance on the size of the belief externality on average across all workers. However, there is also some evidence to suggest that employer learning is faster for high-productivity workers. For example, Arcidiacono, Bayer and Hizmo

30These data come from a firm in the United States, first analyzed by Baker, Gibbs and Holmstrom (1994).
(2010) find faster learning for college graduates, which suggests a larger externality at the low end; and Lindqvist and Westman (2011) show that non-cognitive skills – likely the hardest for employers to learn – are most important at low levels of income.

In Appendix H, I build on Arcidiacono et al.’s (2010) work by providing more direct evidence on how learning varies over the productivity distribution. Taking AFQT as a proxy for productivity, I adapt equation 20 by interacting the variables of interest with indicators for whether a worker’s AFQT score is above or below the median. I then estimate the interacted equation using NLSY79 data (Bureau of Labor Statistics 2016). Below the median, I find strong evidence of learning: the weight on AFQT rises with experience, and the weight on education falls. Above the median, there is less evidence of learning: higher AFQT scores immediately raise wages, while the coefficient on the interaction between AFQT and experience is close to zero. I take this evidence into account below.

There is also evidence to suggest that employer learning is more prevalent in some occupations than others. For example, Mansour (2012) finds that learning is especially important in health-diagnosing, personal services and secretarial occupations; but unimportant for technicians, mail distribution workers and construction laborers. Light and McGee (2015) focus on skills. They find empirical support for learning about all skills. But they also find that employers learn to screen workers on some skills (e.g., mathematical skills) if they are particularly important in a given occupation, but that they cannot do so effectively for other skills (e.g., paragraph comprehension). Future work could consider the implications of this type of heterogeneity for optimal taxation.

**C. Evidence on the Response of Productivity to Returns**

The second piece of evidence I require is an estimate of the relative responsiveness of productivity, compared to taxable income. There is considerable uncertainty regarding how strongly human capital investments respond to labor market returns, which motivates the sensitivity analysis below.\(^{31}\) However, there are several available estimates of short-run effects, as well as growing evidence of longer-run investment impacts.

There are three papers that provide quantitative measures of the relative responsiveness of human capital investments. All are broadly consistent. First, Blomquist and Selin (2010) provide a short-run estimate using a difference-in-differences approach and a tax reform in Sweden: their results suggest that around three quarters of the response of taxable income comes through wages.\(^{32}\) Second, Sumiya (2020) estimates wage and labor supply responses of roughly equal magnitude, with the wage responses building over several

---

\(^{31}\)The qualitative implications of the model are robust, but the quantitative importance of the belief externality scales with the relative importance of human capital.

\(^{32}\)This may be conservative since Blomquist and Selin cannot capture long-run human capital responses.
years. Third, Trostel (1993) provides a calibration which suggests that 60 to 80 percent of the long run response of income to taxation comes from labor productivity.

There is also quasi-experimental evidence documenting very long run responses of human capital investments. Most closely connected to taxation, Abramitzky and Lavy (2010) study the reduction in effective marginal tax rates that occurred when Israeli kibbutzim shifted from equal-sharing to productivity-based wages.\footnote{Kibbutzim are small collective communities in Israel.} They find that the reform led to sharply higher graduation rates and test scores. In addition, Kuka, Shenhav and Shih (2018) study the introduction of the Deferred Action for Childhood Arrivals (DACA) program, which increased returns to human capital investment. They show that high school graduation and college attendance rates increased markedly for eligible individuals.

In some cases, changes in the economic environment can be used to calculate an elasticity of formal education with respect to marginal benefits. Bleakley (2018) calculates several such estimates. In most cases, variation in the returns to education comes from mortality risk rather than taxation. For example, Bleakley calculates an elasticity of 0.7 based on Jayachandran and Lleras-Muney’s (2009) study of Sri Lanka in the 1950s when maternal mortality fell due to policy interventions and medication. Similarly, Fortson (2011) studies the spread HIV in Africa, estimating an elasticity of 0.9; this is in line with the response to AIDS treatment (Baranov and Kohler 2018). In the United States and Canada, Oster, Shoulson and Dorsey (2013) find an elasticity of 1.3 in response to diagnoses of Huntington’s disease, although Stoler and Meltzer’s (2013) results imply 0.4 with different data. Bleakley and Hong (2013) focus instead on declines in the return to skill for white Southerners following the Civil War, and find an elasticity between 0.6 and 1.3.

An additional strand of the literature focuses on expectations about human capital returns. Of particular relevance is Delavande, Del Bono and Holford (2020), who show that perceived labor market returns are an important driver of unobservable time allocation choices such as university attendance and hours of study, as well as non-academic investments. These are precisely the types of unobservable investments that make productivity hard to observe even conditional on formal education choices. Others have shown that cross-sectional data on expectations about the returns to undergraduate or postgraduate education explain both individual choices and gaps between individuals of different backgrounds (Boneva and Rauh 2018, Boneva, Golin and Rauh 2021, Wiswall and Zafar 2021).\footnote{Even at very early ages, differences in perceived returns to parental time investments in children explain a large portion of socioeconomic gaps in such investments (Cunha 2017, Attanasio, Boneva and Rauh 2020).} Furthermore, human capital investments have been shown to increase when students are informed about the returns to additional schooling (Jensen 2010).

Finally, MacLeod et al.´s (2017) aforementioned study of college exit exams also pro-
vides evidence of improvements in average productivity. As employers receive more information, and wages begin to more closely track ability, average wages rise by seven percent given the same formal education. This rise in wages is consistent with a response of human capital investment to the higher return to ability, although it could also be explained by improved matching between workers and tasks.

D. CALIBRATION TO THE UNITED STATES ECONOMY

I now calibrate the model to match both the evidence above and the empirical United States wage and income distributions. I start with three scenarios which make different assumptions about the relative importance of human capital and the overall responsiveness of taxable income. Table 2 summarizes the assumptions needed and my choices for them. Part H then considers two additional scenarios.

Table notes. This table summarizes the key assumptions underlying the three benchmark simulations. Objects in the top panel are calibrated directly, while the target objects in the bottom panel are implied. Both exercises assume that there is no separate expenditures that do not enter individual utilities. See text and Appendix I for further details and simulations with alternative calibrations.

The wage schedule that I target is the Pareto log-normal approximation provided by Mankiw, Weinzierl and Yagan (2009) using March CPS data. However, a wage schedule cannot be assumed directly, since equilibrium wages are jointly implied by productivity and signal distributions. The approach I take is to posit a conditional signal distribution, \( f(\theta|q) \). Then I find a productivity distribution that yields a wage distribution as close as possible to the target.\(^{35}\) As panel (a) of Figure 8 shows, this is successful. Importantly, the

\(^{35}\)Specifically, I parameterize a Champernowne (1952) distribution – a family of bell-shaped distributions designed to fit empirical income distributions – to minimize the Kullback-Leibler divergence between the equilibrium and target productivity distributions under the 20 percent tax from which the simulation starts.
Pareto statistic of the right tail is replicated in addition to the overall shape.

Next, I choose a signal distribution so that, on average, a worker who increases her productivity by one dollar receives an 85 cent higher expected wage. This is at the conservative end of the estimates in Table 1. In line with my empirical results on heterogeneity in learning, I also ensure that high income workers capture most of the gains from their human capital investment. I achieve these aims by assuming a conditionally log-normal signal distribution with $E(\theta|q) = q$, and with $\text{var}(\theta|q)$ linearly increasing in $q$. Panel (b) of Figure 8 displays the results.

Utility is quasilinear in consumption, with the parameters chosen to target income, wage and labor supply elasticities. In the baseline scenario, I set $\varepsilon_l = 0.25$, in line with estimates of the intensive-margin labor supply elasticity (e.g., Chetty 2012). Next, I calibrate the equilibrium (“long run”) elasticity of each variable with respect to the retention rate, $1 - T'$. These elasticities cannot be directly assumed, but they are closely connected to the labor supply elasticity and the elasticity of productivity with respect to investment, $\beta$. I choose a value for $\beta$ that produces long-run elasticities of average wages and labor supply of 0.7 and 0.4 respectively. This implies that around 60 percent of the long-run response of taxable income comes from labor productivity, which is at the low end of the estimates above. The same estimates imply an overall elasticity of taxable income of 1.1.

The elasticity of taxable income in the baseline scenario is large, although it is in line with recent estimates by Mertens and Montiel-Olea (2018). This is because it incorporates the long-run response of human capital investment, as well as a multiplier effect that arises because workers with higher wages work more, and working more raises the return to investment. To evaluate the implications of a lower elasticity, the second benchmark changes $\beta$ and $\varepsilon_l$ so the elasticity of taxable income is 0.7. An additional scenario in part H considers an even lower elasticity (0.3). Finally, since there remains uncertainty about how much of the response of taxable income comes from human capital, the third benchmark changes $\beta$ and $\varepsilon_l$ so that more of the response comes from labor supply.

E. Solving for Optimal Taxes

To simulate the model, I start with an initial tax schedule, $T_0$, and a known equilibrium. I then consider adopting an alternative tax schedule, $T_1$, under which the marginal tax rate is raised or lowered by $\Delta T'$ over a range of incomes from $\zeta$ to $\zeta$.

---

36 Results with risk averse consumers are available in Appendix I; they have similar implications.
37 For instance, the wage elasticity in Section 3’s example is $\beta(1 + \varepsilon_l)/(1 - \beta(1 + \varepsilon_l))$. Given $\varepsilon_l$, the elasticity is thus fully determined by $\beta$. But with non-linear taxation, equilibrium responses vary with the tax system. The statistics here are the responses of average wages and labor supply to a change to a flat tax.
38 This is at the low end of the wage elasticity estimates discussed above. A low estimate is conservative, since a higher elasticity implies a larger belief externality. Nonetheless, I consider smaller values below.
Figure notes. These figures show the implications of the calibration procedure for the simulation described in Section 5. Further details of the calibration procedure are available in Appendix I. Panel (a) compares the empirical (target) and approximate (simulated) wage distributions. Panel (b) shows the relationship between expected wages and productivity in the baseline economy. On average, a worker who increases her productivity by one dollar per hour receives an 85 cent increase in her expected wage.
\[ T'_1(z) = \begin{cases} 
T'_0(z) + \Delta T' & \text{if } z \in (\underline{z}, \overline{z}) \\
T'_0(z) & \text{otherwise}
\end{cases} \]

Given \( T_1 \), I re-calculate the expected utility of workers with each level of productivity, and let workers adjust their human capital investments. Next, I re-solve for employer beliefs, and wages, given the new productivity distribution. From here, I repeatedly re-optimize human capital decisions and re-calculate beliefs until a fixed point is obtained. At this fixed point, employers’ beliefs and workers’ investment decisions are mutually consistent. Finally, I calculate expected utility for each individual, weight using the social welfare function, and adopt the new tax schedule if the welfare gain is positive.

This is the procedure that underlies Figures 2, 6 and 7. It can be continued repeatedly, starting with large perturbations and ending with smaller ones, until the gain to each marginal perturbation is zero. At this point, expression 18 of Proposition 3 is zero. I refer to this final tax schedule as optimal. It is important to note here that this procedure cannot guarantee global optimality, although many different starting points lead to the same equilibrium (see Appendix Figure I1). The procedure mirrors the process of real tax reform and reliably leads to substantial welfare gains. Further details of this process and the specific simulations below are available in Appendix I.

**F. A Naïve Benchmark for Comparison**

As a benchmark against which to compare the optimal tax schedule, I imagine a naïve social planner who neglects to take into account the fact that part of the response of wages to a change in the tax system arises due to an externality. This means that she neglects the novel effect of a perturbation of the tax schedule, \( BE(z) \). Instead, she simply equates the fiscal externality and the mechanical effect, as would be the correct approach in the equivalent model with perfect employer information.

Comparison of the naïve and optimal tax schedules facilitates an assessment of the quantitative importance of the belief externality. This is similar in spirit to Rothschild and Scheuer’s (2013) concept of a self-confirming policy equilibrium (SCPE), which involves solving for an allocation that satisfies a social planner who ignores the endogeneity of wages.\(^{39}\) However, the planner is more sophisticated here in that she is aware when measuring the fiscal externality that she must take into account both wage and labor supply responses. Similarly, she knows that the mapping from productivity to wages is stochastic. The only thing that the planner is unaware of is that part of the change in equilibrium wages arises due to a spillover that workers ignore when re-optimizing.

\(^{39}\)The SCPE could be used as an alternative benchmark, but ignoring the endogeneity of wages is unappealing in a model with human capital, and the exercise would exaggerate welfare gains.
**Figure 9: Optimal Non-linear Taxation**

(a) Non-linear Taxation (Baseline)

(b) Non-linear Taxation (Lower Taxable Income Elasticity)

(c) Non-linear Taxation (Lower Human Capital Share)

(d) Effects on Welfare of Changing the MTR (Baseline)

*Figure notes.* This figure shows the results of the three benchmark simulations described in Table 2. The solid red lines in panels (a), (b) and (c) show the optimal tax schedules, while the dashed blue lines show tax schedules that would be accepted by a naïve social planner who sets the sum of the mechanical effect and fiscal externality equal to zero. Panel (d) shows a decomposition of the effects of small marginal tax cuts in each tax bracket around the optimum in the baseline scenario. A further decomposition of the belief externality itself is available in Appendix I. The tax function is discretized into $20,000 brackets. Details of the procedure are available in Appendix I.
G. Quantitative Results

Figure 9 shows the optimal and naïve tax schedules. The red line in each figure is a tax schedule which ensures that expression 18 is zero, so that there is no welfare gain from a small perturbation in any tax bracket. The blue line would satisfy a naïve social planner, because the mechanical effect and the fiscal externality sum to zero. In all three cases, marginal tax rates are generally much lower under the optimal than the naïve schedules, reflecting the fact that the belief externality provides the planner with an incentive to encourage investment by lowering marginal tax rates.

Both the naïve and optimal tax schedules have the familiar “U” shape, which comes from the trade-off between the mechanical effect and the fiscal externality when the income distribution has a Pareto right tail (Diamond 1998). This shape is now accentuated under optimal taxation because the belief externality is more important at intermediate incomes (see panel (d) of Figure 9). As foreshadowed by the theory, this is partly because a given wage impact from the externality is less important at high incomes where social welfare weights are low, and at low incomes where little labor is supplied; and in part the shape is due to variation in the wage impact itself. The shape of the impact of the externality differs across the three scenarios because – holding fixed the wage distribution – changing $\epsilon_l$ and $\beta$ produces different income and underlying cost distributions.

At very high incomes, the optimal tax schedule is above the naïve tax schedule. This is for two reasons. First, as income rises, the belief externality becomes arbitrarily small so that the planner simply trades off the mechanical effect and the fiscal externality. Second, changes in marginal tax rates at high incomes shift investment incentives throughout the productivity distribution; and most of those who respond now face lower tax rates most of the time – implying a smaller fiscal externality from their re-optimization.

At very low incomes, optimal marginal tax rates are also higher in two of the three scenarios. This is due to the increased value of transfers to the poorest workers. Specifically, as taxes are lowered throughout most of the income distribution, most workers experience an increase in expected utility, but those at the bottom do not (see Figure I10). Relative welfare weights therefore rise at very low incomes. In turn, this increases the mechanical welfare gain from raising marginal taxes at the very low end of the income distribution.

The shape is further amplified because the belief externality scales with the retention rate, $1 - T'(z)$. Appendix I provides a decomposition exercise that sheds more detailed light on how the incidence of the externality shapes its importance in different parts of the income distribution.

Specifically, a more disperse income distribution is implied by a higher value of the elasticity of labor supply, and a more disperse underlying cost distribution is implied when $\beta$ is smaller.

Figure I2 shows results for even higher incomes. The naïve and optimal tax schedules are close to each other at the very top because those affected by the belief externality receive low marginal welfare weight. At the highest levels of income, both schedules therefore approach the revenue-maximizing rate.
distribution, since doing so redistributes income to the lowest-income individuals.

Relative to some other results in the literature (e.g. Saez 2001), even the naïve tax schedule is lower. This is partly due to the larger income elasticity, which includes human capital responses. However, a comparison of panels (a) and (b) in Figure 9 reveals that this is only part of the reason. The assumption that agents are risk-neutral also contributes. This avoids income effects, and greatly simplifies the exposition, but allowing for risk aversion raises the levels of both schedules. Appendix I therefore provides results from a calibration in which workers are risk averse and the social welfare function is linear.

In the baseline scenario, the welfare gain from taking into account the belief externality is equivalent to raising the consumption of all workers by one percent, holding labor supply and investment fixed. There are smaller gains in the other two scenarios: 0.6 percent with a lower income elasticity, and 0.5 percent with a smaller human capital share. Note that these are not Pareto improvements: individuals with moderate levels of productivity experience large gains in utility, but very low skill workers are worse off because lower marginal tax rates imply less redistribution (see Figure I10). In particular, the transfer to the lowest-income worker is five percent smaller in the baseline scenario. Workers with very high productivity are also hurt, because tax rates are higher at top incomes.

H. Alternative Parameter Values

I next evaluate the impact of the belief externality in two additional scenarios, both of which are more conservative. First, I lower the elasticity of taxable income even further. Second, I reduce the size of the externality itself. Figure 10 compares the adjustment made between the naïve and optimal tax schedules in all five scenarios.

The solid black, solid gray and dashed red lines in Figure 10 simply plot the gaps between the optimal and naïve tax schedules in Figure 9. Next, the dotted blue line shows a specification that is similar to benchmark 3 but with an even lower elasticity of taxable income. Finally, the pink dot-dashed line starts from the baseline scenario but makes the employer’s signal of worker productivity more precise. In turn, this implies a smaller externality from human capital investment. Both of these scenarios lead to similarly shaped downward adjustments to optimal tax rates when the belief externality is taken into account. However, the average adjustments to marginal tax rates are smaller.

The results from these five specifications show that the main conclusions of the paper are robust. However, the importance of the belief externality does depend on the parameters, as does the welfare gain from optimal taxation. Mirroring the example in Section 3, the quality of employer information about worker productivity and the relative responsiveness of human capital are particularly important. Large changes in the elasticity of taxable income can also be important, but moderate changes have a muted impact.
Figure notes. This figure shows the impact of the belief externality with alternative parameter values. The black (solid), gray (solid) and red (dashed) lines plot the gaps between the optimal and naïve tax schedules in Figure 9. The dotted blue line is similar to benchmark 3: the elasticity of taxable income is even lower, but the share of the response that comes from human capital is unchanged. The pink dot-dashed line starts from the baseline scenario but makes the employer’s signal of worker productivity more precise.

6 Extensions of the Model

My final step is to consider extensions. First, I introduce formal education, which the government can subsidize. Second, I let employers observe and use exogenous worker characteristics, which introduces statistical discrimination. Finally, in Appendix F, I let investment play an unproductive ‘pure’ signaling role as well as raising productivity.

A. Formal Education

In my first extension, I introduce formal education. This raises the question of whether an education subsidy could help mitigate the externality from unobservable investment, reducing the need to lower the income tax. However, a formal education subsidy is a poorly targeted instrument. Although it does raise investment in human capital, it also distorts its composition. Moreover, if the two types of investment are correlated, workers invest too much in formal education because it acts as a signal of unobservable investment.\footnote{Similar logic underlies the method used by Lange (2007) to bound the role of job market signaling.} This further pushes toward less subsidization of formal education.

For clarity, I focus again on a tractable example. Both the income tax, $\tau$, and education subsidy, $\tau_e$, are linear. Human capital is a Cobb-Douglas combination of formal education, $e$, and unobservable effort, $x$. Specifically, a worker’s marginal product is $q = e^{\beta \alpha} x^{\beta (1-\alpha)}$.\footnote{Similar logic underlies the method used by Lange (2007) to bound the role of job market signaling.}
so that $\alpha$ measures the relative importance of formal education. Workers have utility:

$$U = (1 - \tau) z - l^{1 + \frac{1}{\varepsilon_l}} - k_x x - (1 - \tau_e) k_e e + R$$  \hspace{1cm} (22)$$

where $R = \tau z - \tau e k_e e$ is a lump sum transfer, taken as given by workers.

Employers see a signal of unobservable human capital investment, which is log-normal:

$$\ln \theta = \ln x + \ln \xi$$

where $\ln \xi \sim N(0, \sigma_\xi^2)$. The investment costs, $k_x$ and $k_e$, are also jointly log-normal, and they may be correlated.

$$\begin{bmatrix} \ln k_e \\ \ln k_x \end{bmatrix} \sim N \left( \begin{bmatrix} \ln \mu_{k_e} - \frac{\sigma_{k_e}^2}{2} \\ \ln \mu_{k_x} - \frac{\sigma_{k_x}^2}{2} \end{bmatrix}, \begin{bmatrix} \sigma_{k_e}^2 & \rho_{k_e \sigma_{k_e} \sigma_{k_x}} \\ \rho_{k_e \sigma_{k_e} \sigma_{k_x}} & \sigma_{k_x}^2 \end{bmatrix} \right)$$  \hspace{1cm} (23)$$

The equations for the optimal tax and education subsidy are similar to Section 3. They capture a trade-off between redistribution and distortion, combined with a correction for the belief externality. However, the equations are scaled now by constants, $M_\tau$ and $M_{\tau_e}$.

**Proposition 4.** For any tax rate, $\tau$, and education subsidy, $\tau_e$, there is an equilibrium in which observable and unobservable human capital investment are jointly log-normal. Assuming this equilibrium is played, the conditions for the optimal tax, $\tau^*$, and education subsidy, $\tau_e^*$, are:

$$\frac{\tau^*}{1 - \tau^*} = M_\tau \begin{bmatrix} 1 - \gamma \\ \varepsilon_{zt} - \gamma (1 - s) \varepsilon_{qT} \end{bmatrix}$$  \hspace{1cm} (24)$$

$$\frac{\tau_e^*}{1 - \tau_e^*} = M_{\tau_e} \begin{bmatrix} 1 - \gamma \\ \varepsilon_{zt} - \gamma (1 - s) \varepsilon_{qT} \end{bmatrix}$$  \hspace{1cm} (25)$$

where: $\gamma = E \left\{ \frac{\psi_{k_e,k_x}}{\psi} \frac{\xi_{k_e,k_x}}{\xi} \right\}$; $\varepsilon_{qT}$ and $\varepsilon_{zt}$ are the elasticities of $q$ and $z$ with respect to $1 - \tau$; and $1 - s$ is the share of the social return to productivity that workers fail to capture due to imperfect employer information. The constants $M_\tau$ and $M_{\tau_e}$ are functions of elasticities (see Appendix G).

It is useful to start by considering the benchmark in which $\sigma_\xi^2 = 0$, in which case employers have perfect information. This case is studied by Bovenberg and Jacobs (2005), who show that $M_\tau = M_{\tau_e}$ and that the tax rate and subsidy are given by:

$$\frac{\tau^*}{1 - \tau^*} = \frac{\tau_e^*}{1 - \tau_e^*} = \frac{1 - \gamma}{\varepsilon_{zt} - \beta \alpha \varepsilon_e}$$  \hspace{1cm} (26)$$

where $\varepsilon_e$ is the elasticity of formal education with respect to $1 - \tau$.

Formal education is optimally made “tax deductible” in this benchmark case. This effectively neutralizes any distortion of formal human capital investments, which is why the cost of taxation in the denominator only captures a distortion to labor supply and
unobservable investment. These results are independent of the importance of formal education, $\alpha$, reflecting that further subsidization of education is not warranted to stimulate unobservable investment even as it becomes more important. The reason is that further subsidization does encourage overall human capital investment, but this benefit is exactly offset by costly distortion to the composition of learning toward formal education.\footnote{If human capital production is not Cobb-Douglas, this result no longer holds exactly, but it holds approximately for a wide range of elasticities of substitution between investments (see Bovenberg and Jacobs 2005).}

When employer information is imperfect ($s < 1$), it is no longer optimal to make formal education fully tax deductible. Instead, the education subsidy is set lower than the tax rate. This is because schooling acts as an unproductive “signal” of imperfectly observable effort due to the correlation between formal and informal investments. Workers thus over-invest in formal education in effort to demonstrate their higher unobservable productivity. This pushes toward a lower education subsidy than otherwise. With a lower education subsidy, the optimal income tax falls slightly as well.

Figure 11 illustrates these results in a parameterized example. The black line shows the tax rate if $x$ and $e$ are uncorrelated in equilibrium. Formal education then plays no unproductive signaling role, and the core result of Bovenberg and Jacobs (2005) is preserved: education is optimally made tax deductible. Still, both the tax and subsidy rise as formal education grows in importance, because more of the overall distortion from the income tax is neutralized by the education subsidy. The blue lines show the tax and subsidy rates when the two investments are correlated. The education subsidy is lower, reflecting a correction because part of the returns to education come from unproductive signaling.

**B. Statistical Discrimination**

In my next extension, I allow employers to observe exogenous characteristics of workers such as race, gender or disability status. In the model, employers statistically discriminate in any situation in which groups differ in their equilibrium productivity distributions. The logic is simple: if productivity distributions differ by group, then employers rationally make different assessments of a worker’s productivity given the same signal.

Take the example in Section 3, but now suppose there are two groups of workers: an advantaged group, $A$, and a disadvantaged group, $D$. The groups are identical except that $\mu^D_k > \mu^A_k$, so that group $D$’s costs are higher than group $A$’s. In equilibrium, the wage and income distributions of $D$ workers are shifted down relative to those of $A$ workers. An audit study would reveal a wage gap between $A$ and $D$ workers with identical signals.

\[
\ln \left( \frac{w(\theta|\pi_A)}{w(\theta|\pi_D)} \right) = (1-s) \ln \left( \frac{\mu^A_q}{\mu^D_q} \right) \tag{27}
\]
Figure 11: Optimal Income Tax and Formal Education Subsidy

Figure notes. This figure shows how the optimal income tax and subsidy vary with the importance of formal education, and the strength of the correlation between formal education and unobservable investment. Mirroring Section 5, $\beta = 0.3$, $\varepsilon_I = 0.6$ and $s = 0.85$ so that the equilibrium elasticity of taxable income is one, and the ratio of the elasticities of wages and income, $\varepsilon_{WT}/\varepsilon_{ZT}$, is 0.6. The strength of the planner’s preference for redistribution, $\gamma$, is set to 0.6; both the tax and subsidy would fall if $\gamma$ were higher.

Specifically, with $s = 0.75$, discrimination would appear to “account for” around one quarter of the overall wage gap between the two groups.

This raises the question of whether discrimination motivates different tax rates for each group. If employers had perfect information, there would be two reasons to do so. First, the elasticity of taxable income, $\varepsilon_z$, may differ between groups; and second, the covariance between incomes and welfare weights, $\gamma$, may differ. Here, there is an additional tagging motive: the belief externality may differ across groups. The question is whether the return to skill is systematically suppressed more for groups who are discriminated against.

A key result is that the size of the externality depends on the dispersion but not the level of investment (see Corollary 1). As a result, a cost disadvantage of this kind does not affect the externality, and does not provide a motive to condition the tax system on group membership. In this sense, statistical discrimination does not itself suggest a lower tax for the disadvantaged group. Fundamentally, this is because the mechanism underlying

\footnote{For discussions of “tagging”, see Akerlof (1978), Kaplow (2007), and Mankiw and Weinzierl (2010). See also Fryer and Loury (2013), who study policies designed to improve the outcomes a disadvantaged group.}
\footnote{There is some evidence to suggest that the return to skill is either lower for black workers than white workers (Bertrand and Mullainathan 2004, Pinkston 2006), or roughly equal (Neal and Johnson 1996).}
\footnote{This conclusion contrasts with subsidies suggested based on models of “self-fulfilling” statistical discrimination (Coate and Loury 1993, Craig and Fryer 2017). The strong prescription from those models stems from three assumptions: (i) investment is binary; (ii) the social benefit to investment is constant; and groups}
statistical discrimination lowers the welfare of the disadvantaged group but distorts the human capital investments of both groups.\textsuperscript{48}

**Corollary 1.** The standard deviation of log wages ($\sigma_q^2$) and signal-to-noise ratio $s = \frac{\sigma_q^2}{\sigma_q^2 + \sigma_\xi^2}$ are pinned down by the following condition.

$$\sigma_q^2 = \left( \frac{\beta}{\beta s (1 + \varepsilon)} \right)^2 \sigma_k^2$$

The optimal tax rate is thus independent of the level of costs $\mu_k$, and does not directly depend on the level of log productivity $\mu_q$.

However, statistical discrimination can also arise for other reasons. For example, suppose that the cost distributions are identical but that the employer’s signal is noisier for group $D$. This also yields statistical discrimination (see Phelps 1972, Aigner and Cain 1977, Lundberg and Startz 1983). And in this case, the belief externality is larger for the disadvantaged group, because employers find it harder to assess the productivity of members of that group. The planner therefore has a new motive to set $\tau_D < \tau_A$.

## 7 Conclusion

A substantial body of evidence suggests that employers have imperfect information about the productivity of their workers. This paper provides a framework to study optimal income taxation in this environment. In the model I develop, employers observe an imperfect signal of workers’ human capital investments. I show how moral hazard caused by Bayesian inference introduces an externality: workers who invest more raise their own wage but also affect employers’ perceptions – and thus the wages – of other workers.

My quantitative results suggest that this new externality is of first-order importance, yet further research on the response of human capital investments to marginal tax rates would be of great value to further refine the quantitative predictions of the model. Taking the externality into account leads to marginal tax rates that are substantially lower on average. This downward adjustment to tax rates is concentrated at intermediate incomes, leading to an amplification of the classic “U” shape of the optimal tax schedule. There is a notable welfare gain from moving to optimal taxation.

My model provides a framework that could be extended to analyze the implications of many other features of the labor market. This could include asymmetric employer

---

\textsuperscript{48}This has implications for how one interprets empirical tests for relative distortions of human capital investments of minority groups specifically if discrimination is statistical in nature (see Appendix A).
learning (Acemoglu and Pischke 1998), an extensive margin of labor supply (Saez 2002), variation in employer learning by occupation (see Mansour 2012), and richer labor market structures including tournaments or other dynamic contracts (Lazear and Rosen 1981, Prendergast 1993). These extensions would preserve the conclusion that wages or utility are compressed, lowering the private return to investment relative to the social return, but they will also lead to other insights.\footnote{Appendix A discusses some of the additional complications and insights that would arise in a dynamic model with repeated interactions between workers and firms.}

The core insight is even more general: inference based on imperfect information disconnects the private and social returns to engaging in positive behavior. For example, police officers interpret the actions of suspects based on their experiences with previous individuals; compliance by one individual may thus reduce the likelihood that an officer uses force against a similar suspect in the future. Likewise, buyers form beliefs about the qualities of goods and services based on past purchases; a good experience may therefore raise a consumer’s willingness to pay for other similar products.\footnote{See Wagner, Banerjee, Mohanan and Sood (2019) for an example of how imperfect information distorts the return to quality in a healthcare setting. Similarly, Bachmann, Ehrlich, Fan and Ruzic (2019) study reputational spillovers among German car manufacturers following the 2015 Volkswagen crisis; and Bai, Gazze and Wang (2019) study reputational effects following the 2008 Chinese dairy industry scandal.}

The approach of this paper could be expanded to provide new insights into these contexts and others.

A Generalizations of the Model
(For Online Publication)

A. Generalizing Contracts

The model in Section 2 assumes that employers offer a wage to workers, as opposed to offering a general contract that specifies both a wage and labor supply. Here, I show that this is not restrictive. The reason is that workers with different types or productivity levels do not differ in their disutility of labor supply, fixing their wage.

To demonstrate this formally, I adopt all the assumptions of the baseline model except that I allow each employer to offer a contract \( C_j = \{ z_j, l_j \} \in \mathbb{R}_+ \times \mathbb{R}_+ = C \) to the worker.\(^{51}\) Each contract specifies a salary \( z_j \in \mathbb{R}_+ \) and a quantity of labor \( l_j \in \mathbb{R}_+ \), which jointly imply a price per unit (wage) \( w_j = z_j/l_j \). As before, the worker accepts her preferred offer, supplies labor and consumes \( c = z - T(z) \).

The worker’s strategy is now a set of two functions – an investment decision and an acceptance rule – which can be written as: \( x : K \times T \rightarrow \mathbb{R}_+ \) and \( A : K \times T \times \Theta \times C_{|J|} \rightarrow J \). Each employer’s strategy is a function that maps signals and tax systems to contract offers \( O_j : \Theta \times T \rightarrow C \). Despite the increased complexity, it remains true that every firm earns zero expected profit. Moreover, contracts can always be equivalently characterized as an offer of a wage \( w_j = w(\theta|\pi) \) equal to the worker’s expected marginal product given the signal \( \theta \), with the worker freely choosing how much labor to supply. In this sense, nothing substantive is changed from the baseline model.

Lemma 3. Fix a realized value of \( \theta \) and assume that \( E[ q|\theta, \pi ] \) is strictly positive and finite given equilibrium beliefs \( \pi(q) \). In any pure-strategy equilibrium: all firms \( j \in J \) earn zero expected profit; the wage \( w_j = z_j/l_j \) implied by every contract offered to the worker is equal to her expected marginal product \( E[ q|\theta, \pi ] \); and the worker’s labor supply \( l_j \) satisfies \( l_j \in L_j^* = \argmax_{\tilde{l}_j \in \mathbb{R}_+} u \left( w_j \tilde{l}_j - T \left( w_j \tilde{l}_j \right), \tilde{l}_j \right) \).

B. Worker Screening

If workers of different types do differ in their disutility of labor supply conditional on their hourly wage, screening by employers using menus of contracts may be possible. To see why, suppose workers’ utility functions take the following quasilinear form:

\[
U_k(c, l, x) = c - h_q(l) - kx
\]

where \( q = Q(x) \).

\(^{51}\)Employers could also offer menus of contracts, but this has no benefit because workers of different productivity levels have no reason to select different contracts.
The assumptions required for screening are documented by Spence (1978), and studied in the context of taxation by Stantcheva (2014). Here, it suffices to study a special case in which taxation is linear and workers have two different equilibrium productivity levels, \( q_i = \{ q_1, q_2 \} \) with \( q_1 < q_2 \). However, the analysis can be generalized to non-linear taxation and many productivity levels (see Stantcheva 2014). Given a signal, \( \theta \), that the employer has observed, let the likelihood that an individual has productivity \( q_1 \) be \( \lambda_1 \), and the like-lihood that they have productivity \( q_2 \) be \( \lambda_2 = 1 - \lambda_1 \). Given these productivity levels, screening requires the following assumptions.

**Assumption 4.**

(i) Labor supply costs are increasing and convex: \( h'_{q_i} (l) > 0, h''_{q_i} (l) > 0 \forall i \).

(ii) Total and marginal disutility of effort are zero with zero labor: \( h_{q_i} (0) = h'_{q_i} (0) = 0 \forall i \).

(iii) The higher type experiences lower total disutility: \( h_{q_2} (l) < h_{q_1} (l) \forall l > 0 \).

(iv) The higher type experiences lower marginal disutility: \( h'_{q_2} (l) < h'_{q_1} (l) \forall l > 0 \).

The reason screening is possible with these assumptions is that higher-productivity workers are willing to work longer hours given the same wage. It is plausible that these assumptions hold in some contexts, although it is unclear whether they hold in general.\(^{52}\)

There are many models of screening. I focus on the Miyazaki-Wilson-Spence (MWS) equilibrium concept (Miyazaki 1977, Wilson 1977, Spence 1978). However, there are other screening models that would be reasonable, and the choice of which one is appropriate is sensitive to assumptions about the timing and nature of contract choices. Specifically, one of the types of MWS equilibria below involves cross-subsidization, and firms would always want to withdraw the loss-making contract if there were a second stage. Nonetheless, MWS is commonly used and has been justified in several different ways (see Fernandez and Rasmusen 1993, Netzer and Scheuer 2014, Mimra and Wambach 2019).

In the MWS framework, firms can offer an arbitrary menu of contracts, each specifying a salary \( z_j \in \mathbb{R}_+ \) and a quantity of labor \( l_j \in \mathbb{R}_+ \). Firms break even on their overall menu of contracts, and choose their menus recognizing that other firms may withdraw any contracts that are unprofitable.

**Definition 2.** *An equilibrium is a set of contracts such that firms break even across their entire menu of contracts, and there is no omitted contract that would be profitable after all contracts made unprofitable by its introduction have been withdrawn.*

\(^{52}\)Indirect support for these assumptions comes from instances in which firms use this type of screening. For example, Landers, Rebitzer and Taylor (1996) study law firms that seem to screen associates by requiring them to work long hours before being promoted.
Formally, the firm solves the following problem.

$$\max_{z_1, z_2, l_1, l_2} (1 - \tau) z_2 - h_{q_2} (l_2)$$

subject to:

$$(1 - \tau) z_1 - h_{q_1} (l_1) \geq (1 - \tau) z_2 - h_{q_1} (l_2) \quad (IC_{12})$$

$$(1 - \tau) z_2 - h_{q_2} (l_2) \geq (1 - \tau) z_1 - h_{q_2} (l_1) \quad (IC_{21})$$

$$\lambda_1 z_1 + \lambda_2 z_2 = \lambda_1 q_1 l_1 + \lambda_2 q_2 l_2 \quad (ZP)$$

$$\lambda_1 z_1 - h_{q_1} (l_1) \geq (1 - \tau) z_1^{RS} - h_{q_1} (l_1^{RS}) \quad (RS)$$

The first two constraints guarantee incentive compatibility: they require that individuals of each productivity level prefer the contract designed for them. The third constraint is a zero profit condition, pooled across both types. The fourth requires that the lower-productivity worker gets at least as much utility as in the “Rothschild-Stiglitz” separating allocation (Rothschild and Stiglitz 1976); this precludes possible profitable deviations by firms that would otherwise arise (see Miyazaki 1977).

For simplicity, I assume labor supply is isoelastic, which ensures that there is an adverse selection problem for all $\tau$ if there is an adverse selection problem for $\tau = 0$. The solution is provided by Stantcheva (2014), which is adapted and restated here.

**Proposition 5.** For any tax rate $\tau$, the profit constraint (ZP) is binding and the second IC constraint (IC_{21}) is slack. With isoleastic labor supply, the first IC constraint (IC_{12}) binds. The low type works an efficient amount of hours, $h_{q_1}^* (\tau)$. There are two possible configurations.

(i) If the share of low-productivity types is high, $\lambda_1 > \tilde{\lambda}_1 (t)$: the RS constraint binds, each worker earns her marginal product, and there is full separation. The higher-productivity type works more than the efficient level, with her labor supply characterized by:

$$q_1 l_{q_1}^* (\tau) (1 - \tau) = q_2 l_{q_2} (\tau) (1 - \tau) - (h_{q_1} (l_{q_2} (\tau)) - h_{q_1} (l_{q_1}^* (\tau))).$$

(ii) If the share of low-productivity types is low, $\lambda_1 \leq \tilde{\lambda}_1 (t)$: the RS constraint does not bind, and there is cross-subsidization from high to low productivity workers. The high-productivity type works more than is efficient, with her labor supply characterized by:

$$h_{q_2}' (l_{q_2} (\tau)) = (1 - \tau) \lambda_2 q_2 + \lambda_1 h_{q_1}' (l_{q_2} (\tau)).$$

In both of these cases, the utilities of workers with different productivity levels are
compressed relative to an economy with symmetric information. In case (i), the hourly compensation of each worker is equal to her marginal product. However, the higher type’s utility is lowered because her labor supply is distorted away from her optimum to ensure that low productivity workers do not want to pretend to have high productivity. In case (ii), this remains the case, but high-productivity workers cross-subsidize the wage of low-productivity workers as well.

From the point of view of the human capital investments that are the focus of this paper, this compression of workers’ utility levels acts in the same way as the wage compression that occurs due to Bayesian belief formation when screening by firms is not possible. The utility gain from increasing one’s productivity is lower than it would be if employers could directly observe productivity, which undermines a worker’s incentive to acquire human capital, and implies a spillover when workers invest.

C. REPEATED INTERACTIONS IN THE LABOR MARKET

An important simplification embedded in the model in Section 2 is that workers invest in human capital once, and then interact with employers once in the labor market. In reality, human capital investment and labor supply decisions are made repeatedly. As discussed in Section 5, evidence suggests that employers gradually learn a worker’s productivity, and that the return to a worker’s initial level of skill therefore increases over time. In this appendix, I briefly discuss the implications of this.

Starting with the thought experiment in Section 5, let \( q \) be the worker’s human capital and assume human capital investment occurs before entry into the labor market. (Generalizations follow below.) However, her marginal product, \( MP_t(q) \), may depend on experience, \( t \). In each period, let employers see a different signal \( \theta_t \in \Theta_t \), which may become arbitrarily precise over time. The worker is still paid her expected marginal product, \( E(MP_t(q)|\theta_t, \pi) \), and her discount factor is \( \delta \).

If utility is quasilinear, taxation is linear and labor supply is perfectly inelastic, the fraction of the social return to increasing \( q \) that the worker captures is:

\[
\frac{\sum_{t=0}^T \delta^t \int_{\Theta_t} E(MP_t(q)|\theta_t, \pi) \frac{\partial f_t(\theta_t|q)}{\partial q} d\theta_t}{\sum_{t=0}^T \delta^t \frac{\partial MP_t(q)}{\partial q}}
\]

(30)

where \( f(\theta_t|q) \) is the conditional distribution of the period \( t \) signal.

The expression on the right of equation 30 is what I use in the calibration in Section 5. It is the present-discounted private return to higher productivity divided by the present-discounted social return. The expression takes into account the fact that employers gradually learn a worker’s productivity, so that \( E(MP_t(q)|\theta_t, \pi) \) approaches \( MP_t(q) \) and the
worker is fully remunerated for her productivity later in life. Nonetheless, at earlier stages in her career – which are more important due to discounting – the marginal private return is lower than the social return. In addition, all my results take into account the fact that workers’ tax rates, labor supplies and welfare weights change with their wage.

If human capital investments were spread out over the lifecycle, the model would become more complex. The learning externality would then be present in every period for the marginal investment, raising the question of how taxes should vary over the lifecycle. On one hand, the fact that investment is still likely be concentrated at earlier ages suggests that the externality would be more important – and taxes lower – at younger ages. But on the other hand, the externality is exacerbated for later investments, all else equal. The reason for this is that a worker’s marginal investment decision can be predicted based on behavior in previous periods, which reduces the weight placed by employers on any signals of contemporaneous investment. This mechanism is likely to push toward lower taxes at older ages, to the extent that human capital investment remains important.

The model could be extended further still, to accommodate possibilities that arise in a dynamic context. For example, with repeated interaction, employers might find a way to provide incentives with dynamic contracts. There are many versions of this, which generally involve workers effectively being remunerated in later periods for having had higher productivity in earlier periods than was expected at the time (and vice versa). Such dynamic incentives would need to be supported by commitment power or reputation-building, and many such models involve workers agreeing to work for less than their marginal product in earlier periods (possibly implying negative initial wages). This is plausible in some settings, which makes this a rich but complex direction for future work.

D. Unequal or Asymmetric Learning

The model discussed throughout this paper features symmetric information across employers. An alternative assumption would be that incumbent employers have more information about a worker’s productivity than do other firms. Acemoglu and Pischke (1998) is one example. They model learning more more simply than in this paper, focusing on the asymmetry. Specifically, a worker’s first-period employer knows her productivity in the second period, but outside employers do not.

The key result of Acemoglu and Pischke (1998) is that the incumbent employer has ex-post monopsony power because of their informational advantage, and earns a profit. Importantly, that profit is increasing in a worker’s skill. In turn, this produces the motivation for a firm to train its workers that is the focus of their paper. However, the flip-side is that a worker’s wage increases by less than her skill despite the fact that her productivity
is known with certainty by the incumbent firm in the second period. This means, in turn, that there would be less incentive for the worker to invest in her own skill.

If the model here incorporated asymmetric learning, it would feature a similar effect. Learning itself would mean that the relationship between expected productivity and skill would be flatter than the relationship between true productivity and skill. That is why there is under-investment in the present paper. Asymmetric learning would lead wages to be further compressed even relative to expectations, causing a further distortion.

**E. Structural Changes in the Labor Market**

The framework in this paper has implications for empirical tests designed to detect discrimination and its effects. Here, I consider the results of Hsieh, Hurst, Jones and Klenow (2019) who show that women and black men have chosen increasingly high-skilled occupations over the past 60 years, converging to a set of choices that is more similar to white men. Building on this observation, they ask how much of GDP growth over this period can be explained by falling barriers such as discrimination which had previously prevented women and black men from choosing occupations that reflected their comparative advantage. They draw a distinction between two types of barriers: those in labor markets and those in education markets.

Hsieh et al. (2019) link these two types of barriers directly to a “taste-based” discrimination framework in the spirit of Becker (1957). That framework provides a microfoundation for two types of implicit “taxes” on workers from each disadvantaged group, relative to white men. First, due to prejudice against hiring them, members of the disadvantaged workers are paid less per efficiency unit than white men: Specifically, the ratio of the minority to white male wage is $1 - \tau_{i,g}^w$. Second, there is a prejudice against providing educational services to disadvantaged workers, so that their cost of attaining human capital is $1 + \tau_{i,g}^h$ higher than white men. These wedges take much the same form as a tax ($\tau_{i,g}^w$) on minority income and tax on their educational inputs ($\tau_{i,g}^h$). The “taxes” distort educational investments, and reduce utility levels. In turn, this deters members of the disadvantaged groups from entering the labor force or choosing high-skill occupations.

My model also features distortions to human capital investments due to implicit “taxes”. When I introduce exogenous worker characteristics in Section 6 Part B, those distortions may well vary between different groups. As I show, the model then produces statistical discrimination against disadvantaged groups. Specifically, there are two groups: advantaged workers ($A$) and disadvantaged workers ($D$). There only difference between the groups is that disadvantaged workers have proportionally higher investment costs. To put this in the framework of Hsieh et al. (2019), this cost disadvantage is indistinguish-
able from saying that disadvantaged workers have the same distribution of investment costs as majority workers but face a “tax” of $1 + \tau^h_{ig}$ on those investments.

There is also a “tax” in the labor market. The expected wage of a disadvantaged worker is lower than that of an advantaged worker with the same productivity level. The fraction of the overall wage gap between the two groups explained by that wedge is $1 - s$.

$$\ln \left( \frac{E(w \mid q, A)}{E(w \mid q, D)} \right) = (1 - s) \left( \frac{E(w \mid A)}{E(w \mid D)} \right)$$

(31)

Following Hsieh et al. (2019), we can let $\tau^w_{ig} = 1 - s$ be the tax wedge from labor market discrimination. In many respects, this wedge is again very similar to the wedge in the taste-based discrimination framework above.

At this point, we are in a position to examine the distortion to human capital investments from the two “taxes”. And it is here that we find a stark deviation from Hsieh et al. (2019). Unlike their taste-based discrimination framework, the entire gap in productivity levels is explained by the human capital rather than labor market discrimination.

$$\frac{q_B}{q_{AA}} = \left( \frac{1}{1 + \tau^h_B} \right)^{\frac{\beta}{1-\beta}}$$

(32)

The reason for this is that statistical discrimination here is “rational” in the sense that it reflects a true gap in human capital. In the labor market, one would observe that a fraction $s$ of the overall log wage gap between the groups is explained by an individual’s own gap in the signal they send to employers (which reflects their own true productivity). A fraction $1 - s$ is explained by labor market discrimination, but that discrimination also reflects a gap in productivity between the two groups.

At this point, we can turn our attention toward the empirical identification strategy of Hsieh et al. (2019). The fundamental logic of their analysis is that: (i) human capital disadvantages are reflected in a cohort’s outcomes in all time periods, because investments are locked in at an early stage; and (ii) labor market barriers are reflected in outcomes in a given time period for all cohorts at a point in time because (for example) employers’ prejudice-based discrimination does not distinguish between cohorts.

Here, there is another sharp divergence between the taste-based discrimination model Hsieh et al. (2019) use to interpret their results, and the statistical discrimination model. Rational statistical discrimination implies that belief formation should occur within a demographic cell, so that discrimination is proportional to the gap in human capital between white male and disadvantaged workers in that cohort. In other words, labor market ac-
tors who statistically discriminate rationally distinguish between cohorts, and in a way that is inseparable from direct human capital barriers. Regardless of the ultimate source of the gap in outcomes between advantaged and disadvantaged workers in the statistical discrimination model (e.g., cost disadvantages, differences in screening technologies, or self-fulfilling disparities), the conclusions from Hsieh et al.’s (2019) analysis would therefore always be that distortions arise due to a barrier to human capital formation.

The final point to note is that there is a distortion to human capital formation in my model that affects both the advantaged and disadvantaged group: both groups under-invest in human capital because of the belief externality. However, Hsieh et al. (2019) normalize the distortion to zero for white men. This observation is important because it implies that there may be misallocation for all groups even if there is no differential misallocation across groups.

F. LINEAR TAXATION WITHOUT PARAMETRIC ASSUMPTIONS

Without the parametric assumptions in Section 3, the analysis of linear taxation closely follows the analysis of non-linear taxation in Section 4. Moreover, the same logic applies at an equilibrium other than the log-normal one considered in Propositions 1 and 2. In fact, the analysis is identical except that the tax system is restricted to be linear.

As in Section 4 then, let \( w(\theta | \pi) \) be the wage of a worker with signal realization \( \theta \). Similarly, those workers have average welfare weight \( \psi(\theta) \), labor supply \( l(\theta | \pi, T) \) and income \( z(\theta | \pi, T) \). The density of workers with type \( \theta \) is \( f(\theta) \). Finally, we need to define \( \varepsilon_{\pi}(\theta) \) as the elasticity of the productivity of workers with signal \( \theta \) with respect to \( 1 - \tau \).

Putting all of that together, we obtain the same optimal tax formula except that the belief externality is generalized as follows:

\[
\frac{\tau^*}{1 - \tau^*} = \frac{1 - \alpha}{\varepsilon_z} - \int_{\theta} \psi(\theta) \left[ \frac{z(\theta | \pi, T)}{z} \frac{\varepsilon_{\text{BE}} w(\theta) \varepsilon_{\pi}(\theta)}{\varepsilon_{\pi}(\theta) \varepsilon_z} \right] f(\theta) \, d\theta
\]

where:

\[
\varepsilon_{\text{BE}} w(\theta) = \frac{dw(\theta | \pi)}{d(1 - \tau) w(\theta | \pi)} \frac{1 - \tau}{\varepsilon_q}
\]

is the change in the wage paid given signal realization \( \theta \).

The log-normal equilibrium in Section 3 is a special case. First, the response of productivity is uniform, so that \( \varepsilon_{\pi}(\theta) = \varepsilon_q \). Second, the fraction of the return to investment that workers capture is a constant: specifically, \( \varepsilon_{\text{EXT}} w(\theta) / \varepsilon_{\pi}(\theta) = 1 - s \) for all \( \theta \). If we impose both of these restrictions here, we are left with the same formula as in Proposition 2.

This highlights the key difference in general. Compared to the log-normal equilibrium,
the belief externality will be larger (and the optimal tax lower all else equal) if there is a
greater response among workers for whom the externality is larger, or if the externality
of those who respond disproportionately affects workers with higher incomes and higher
welfare weights. This closely mirrors the discussion of incidence in Sections 4 and 5 of the
paper with non-linear taxation, with the main difference being that non-linear taxation is
not available to respond to such differences across the distribution.

B Continuity and Stability
(For Online Publication)

A. Continuity of Investment Responses

In this appendix, I discuss the conditions required for equilibrium indeterminacy to be
avoided, and for a given equilibrium to shift continuously in response to the pertur-
bations that I consider. Assume that there is a finite number of cost types, indexed by
i = 1, . . . , |K|, let x be the vector of investment decisions x_i, and define q_i = Q(x_i).

For each i, Assumption 3 ensures that the following binding first-order condition char-
acterizes the optimal investment decision.

\[ \lambda_i (x, T) = Q'(x_i) \int_{\Theta} v(\theta|\pi, T) \frac{\partial f(\theta|q)}{\partial q} \bigg|_{q=q_i} d\theta - k_i = 0 \]  (35)

Differentiating \( \lambda_i (x, T) \) with respect to \( x_j \), we obtain the effect of higher investment by
type j on the investment returns of type i. There are two cases:

\[ \frac{\partial \lambda_i}{\partial x_j} (x) = \begin{cases} \lambda^q_i + \lambda^w_{ij} & \text{if } i = j \\ \lambda^w_{ij} & \text{if } i \neq j \end{cases} \]  (36)

where \( \lambda^q_i \) is type k’s second-order condition, and \( \lambda^w_{ij} \) is the effect via employer beliefs.

\[ \lambda^q_{ii} = Q''(x_i) \int_{\Theta} v(\theta|\pi, T) \frac{\partial f(\theta|q)}{\partial q} \bigg|_{q=q_i} d\theta + Q'(x_i)^2 \int_{\Theta} v(\theta|\pi, T) \frac{\partial^2 f(\theta|q)}{\partial q^2} \bigg|_{q=q_i} d\theta \]  (37)

\[ \lambda^w_{ij} = Q'(x_j) \int_{\Theta} u_c(\theta) \left[ 1 - T'(z(\theta|\pi, T)) \right] l(\theta|\pi, T) \frac{\partial w(\theta|\pi)}{\partial q_j} f(\theta|q_i) d\theta \]  (38)

Letting \( p(k_j) \) be the probability of drawing type k_j, the equation for \( \frac{\partial w(\theta|\pi)}{\partial q_j} \) is as follows.

\[ \frac{\partial w(\theta|\pi)}{\partial q_j} = \left( f(\theta|q_j) + [q_j - w(\theta|\pi)] \frac{\partial f(\theta|q)}{\partial q} \bigg|_{q=q_j} \right) p(k_j) \]  (39)
The partial derivatives (equation 36) can be arranged to form the Jacobian $\mathcal{J}_{f,x}$.

$$
\mathcal{J}_{f,x} = \begin{bmatrix}
\frac{\partial \lambda_1}{\partial x_1} (x) & \ldots & \frac{\partial \lambda_1}{\partial x_{|K|}} (x) \\
\vdots & \ddots & \vdots \\
\frac{\partial \lambda_{|K|}}{\partial x_1} (x) & \ldots & \frac{\partial \lambda_{|K|}}{\partial x_{|K|}} (x)
\end{bmatrix}
$$

Next, let $dc (\theta|\pi, T) = -dT (z (\theta|\pi, T))$ be the Fréchet derivative with respect to $T$ of consumption by a worker with signal $\theta$. The Fréchet derivative of $v (\theta|\pi, T)$ is then:

$$
dv (\theta|\pi, T) = u' (z (\theta|\pi, T) - T (z (\theta|\pi, T))) \times dc (\theta|\pi, T)
$$

And in turn, the Fréchet derivative of $f_i (x, T)$ is given by $df_i (x, T)$.

$$
d\lambda_i (x, T) = Q' (x_i) \int_\Theta dv (\theta|\pi, T) \left. \frac{\partial f (\theta|q)}{\partial q} \right|_{q=q_i} d\theta
$$

These derivatives can be stacked into a $|K| \times 1$ vector $d\lambda (x, T)$.

Providing that $\mathcal{J}_{f,x}$ invertible, the Implicit Function Theorem implies that there is a neighborhood around $x$ and $T$ in which there is a unique Fréchet differentiable function mapping $T$ to $x$, and the response of investments is given by $dx = -\mathcal{J}_{f,x}^{-1} \times d\lambda (x, T)$. As I argue below, invertibility of $\mathcal{J}_{f,x}$ is the generic case.

**B. INVERTIBILITY OF $\mathcal{J}_{f,x}$**

I next show that, if $\mathcal{J}_{f,x}$ is not invertible, it can be rendered invertible by an arbitrarily small perturbation to the investment technology $Q (x)$, which preserves both the key properties of that technology and the existing equilibrium. Moreover, starting with any equilibrium in which $\mathcal{J}_{f,x}$ is invertible, this clearly remains the case after a similarly small perturbation. In these two senses, invertibility of $\mathcal{J}_{f,x}$ is generic.

First, I construct a parameterized family of functions, $\tilde{Q} (x|c)$, where $c$ is a vector of strictly negative real numbers $c_1, \ldots c_{|K|}$. Each function in this family retains the key properties of $Q (x)$, but the second derivative of $\tilde{Q} (x|c)$ evaluated at $x_j$ is $c_j$.

1. Take each $x_j$ and define a narrow domain $x_j \pm r$ where $r > 0$ is arbitrarily small. On this domain, define a function $B_j (x|c_j) = Q (x_j) + Q' (x_j) (x - x_j) + \frac{1}{2} c_j (x - x_j)^2$. $B_j (x|c_j)$ has the same level and derivative as $Q (x)$ at $x_j$, but $B''_j (x_j|c_j) = c_j$.

2. Link the functions $B_j (x|c_j)$ to form any twice-differentiable function $\tilde{Q} (x|c)$ with $\tilde{Q} (0|c) = 0$, $\tilde{Q}' (x|c) > 0$, $\tilde{Q}'' (x|c) > 0$ and $\lim_{x \to 0} \tilde{Q}' (x|c) = \infty$. This is always possible, since $r$ is small and $Q$ strictly concave.
3. Let $\tilde{Q}(x|c, \alpha) = \alpha \tilde{Q}(x|c) + (1 - \alpha) Q(x)$ with $\alpha \in (0, 1)$.

Next, I replace $Q(x)$ with $\tilde{Q}(x|c, \alpha)$ in the economy described in Section 2. For any $c$, there remains an equilibrium with the same investment decisions. However, the diagonal elements of the Jacobian $J_{f,x}$ are replaced by:

$$\lambda_{ii}^q = c_i \int_\Theta v(\theta|\pi, T) \left. \frac{\partial f(\theta|q)}{\partial q} \right|_{q=Q(x_i)} d\theta + Q'(x_i)^2 \int_\Theta v(\theta|\pi, T) \left. \frac{\partial^2 f(\theta|q)}{\partial q^2} \right|_{q=Q(x_i)} d\theta.$$

Moreover, $\lambda_{ii}^q$ scales with $c_i$ since $\int_\Theta v(\theta|\pi, T) \left. \frac{\partial f(\theta|q)}{\partial q} \right|_{q=q_i} d\theta > 0$. Non-diagonal elements of $J_{f,x}$ are unchanged.

Finally, let $c_j = Q''(x_j) + \varepsilon_j < 0$ where $\varepsilon_j$ are distinct real numbers with $\varepsilon_j < -Q''(x_j)$. For small enough $\alpha$, $\tilde{Q}(x|c, \alpha)$ is an arbitrarily close approximation of $Q(x)$. However, the Jacobian $J_{f,x}$ of the new economy is invertible. Specifically, any two rows that were collinear are no longer collinear; and, since $\alpha$ is small, no two rows are newly collinear.

C. Stability of Equilibria

Restricting the set of equilibria to those that are stable is one way to ensure that the economy does not switch equilibria in response to a perturbation such as that described in Section 5. To define such a notion of stability, suppose that the economy evolves according to the following backward-looking dynamic adjustment process:

$$x_{k,t+1} \in X_{k,t+1}^* = \arg\max_{\tilde{x} \in \mathbb{R}^+} \int_\Theta v(\theta|\pi_t, T) f(\theta|Q(\tilde{x})) d\theta - k\tilde{x}$$

(42)

where:

$$v(\theta|\pi_t, T) = w(\theta|\pi_t, T) l(\theta|\pi_t, T)$$

$$l(\theta|\pi_t, T) \in L^*(\theta|\pi_t, T) = \arg\max_{l_j \in \mathbb{R}^+} u \left( w(\theta|\pi_t) \tilde{l} - T \left( w(\theta|\pi_t) \tilde{l} \right) \right)$$

$$w(\theta|\pi_t) = \frac{\int_K Q(x_{k,t}) f(\theta|Q(x_{k,t})) dG(k)}{\int_K f(\theta|Q(x_{k,t})) dG(k)}$$

In general, this does not necessarily define a unique path for the economy. However, Assumptions 1 to 3 ensure that this is true locally because both $x_{k,t+1}$ and $l(\theta|\pi_t, T)$ are both uniquely pinned down and vary continuously with other agents’ investment decisions.

Thus, letting $\mathcal{E}(T)$ be a set of equilibrium investment decisions, the dynamic adjustment process above can be approximated locally around $\mathcal{E}(T)$ by a first-order linear system $x_{t+1}(T) - \mathcal{E}(T) = B [x_t(T) - \mathcal{E}(T)]$. If all the eigenvalues of the matrix $B$ have moduli strictly less than one, then the equilibrium is locally asymptotically stable. Providing...
that $J_{f,x}$ is invertible (see Part A above) so that there is a locally unique Fréchet differentiable function mapping $T$ to $x$, local asymptotic stability in turn ensures that the economy does not switch equilibria in response to a small change in the tax schedule.

D. Existence of Pure Strategy Equilibria

In this appendix, I discuss the existence of a set of pure strategy equilibria. I begin with a practical observation: fixing any signal technology $f(θ|q)$, there is always a production function $Q(x)$ that satisfies the assumptions in Section 2 while also guaranteeing the existence of an equilibrium with the empirically observed wage distribution, labor supply elasticity and wage elasticity. It can also be ensured that this equilibrium is stable. Indeed, I use these facts in my simulations in Section 5.

Despite the fact that there is always an equilibrium that matches any observed wage distribution, it is important to note that uniqueness is not guaranteed. In fact, there is always a “bad” equilibrium in which no worker invests at all and wages are zero for all signal realizations. This equilibrium is always unstable given the assumptions in Section 2. However, it is not generally possible to rule out the potential for multiple internal stable equilibria. I discuss this issue further in Appendix D.

It is harder to provide general weak conditions for the existence of a stable equilibrium with positive investment in the general model without backing out a set of fundamentals from one that is observed. To see why, let $q^*_i(q)$ be an expected utility maximizing productivity level of type $i$, given that employers believe that the vector of productivity levels is $q$. The assumption that $\lim_{x \to 0} Q'(x) = \infty$ combines with the regularity assumptions on the signal technology to ensure that all individuals’ optimal productivity levels are greater than employers believe them to be: i.e., $q^*_i(q) > q_i$ for all $i = 1, \ldots, |K|$ if $q$ is close enough to zero. If we were also to assume that the marginal return to investment is zero above some $\bar{q}$ (effectively truncating the relevant strategy space), then $q^*_i(q) < \bar{q}$ if employers believe that all workers have productivity level $\bar{q}$. Thus, if $q^*_i(q)$ were globally continuous, we would be guaranteed another equilibrium. The problem is that this need not be the case without restrictions that guarantee concavity of investment returns.

Despite this difficulty in providing general conditions, it is also clear that this is an issue that need not be of great concern. Not only does the calibration in Section 5 back out a well-defined stable equilibrium from the data, but the equilibrium remains well-defined as the optimization algorithm explores many different parts of a multi-dimensional space. In addition, the examples in Section 3 and Appendix D have closed-form solutions. There are many other such examples.
E. Series Expansion, Direct and Indirect Effects

At a stable equilibrium, the investment response can be decomposed into direct and indirect effects of a tax change. First, let $S$ be the diagonal matrix of second-order conditions:

$$ S = \begin{bmatrix} S_1 & \ldots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \ldots & S_{|K|} \end{bmatrix} $$

where:

$$ S_i = Q''(x_i) \int_\Theta v(\theta|\pi, T) \frac{\partial f(\theta|q)}{\partial q} \bigg|_{q=q_i} d\theta + Q'(x_i)^2 \int_\Theta v(\theta|\pi, T) \frac{\partial^2 f(\theta|q)}{\partial q^2} \bigg|_{q=q_i} d\theta $$

The response of investment can then be written as

$$ dx = -\mathcal{J}^{-1}_f SS^{-1} d\lambda(x, T). $$

Letting $I$ be the identity matrix, the matrix $\mathcal{J}^{-1}_f S$ can be rewritten as the following Neumann series, providing that series is convergent.

$$ \mathcal{J}^{-1}_f S = \sum_{k=0}^{\infty} (I - S^{-1} \mathcal{J})^k $$

The matrix $B = I - S^{-1} \mathcal{J}_f$ captures the effect of a change in each worker $i$’s investment decision on the investment decision of each other worker $j$.

Convergence of the Neumann series above corresponds to the case of stability discussed in Part D. At any stable equilibrium, we can thus write the response of the vector of investment choices to a change in the tax schedule as the following infinite series.

$$ dx = -S^{-1} d\lambda(x, T) - \sum_{k=1}^{\infty} B^k S^{-1} d\lambda(x, T) $$

(43)

The intuition here is similar to Proposition 1 of Sachs et al. (2019). The first term captures the partial equilibrium response of investment to a change in the tax schedule. The second term accounts for general equilibrium cross-wage effects.

Each term in the infinite series on the right-hand side of equation 43 captures a “round” of cross-wage effects. The first term measures the indirect effect of partial equilibrium investment responses on investment choices. The $n$th term then captures the successive impact of changes induced by round $n - 1$. At a stable equilibrium, each round is smaller than the last, and the series converges. The sum of all of these rounds of adjustment measures the total shift in equilibrium investments.
C  Beyond the First Order Approach
(For Online Publication)

Proposition 3 provides the derivative of social welfare with respect to a perturbation in the tax schedule, providing that there is a locally continuous selection around the initial point, \((E(T), T)\). I adopted assumptions that ensure this is true for an arbitrary tax system. The proposition also states a condition that holds at an optimum, providing that the planner does not systematically locate at a point where the regularity conditions break down.

In this appendix, I discuss complications that arise when the planner does in fact have a reason to locate at a discontinuity, in which case the derivatives in Proposition 3 are not defined. I also discuss reasons why the planner’s first-order condition is not sufficient for optimality. For expositional clarity, I focus on a particularly simple case of the general model, in which the planner is restricted to a linear tax, labor supply is perfectly inelastic, and investment decisions are binary.\(^{53}\) This greatly simplifies the analysis of this subset of issues, while providing insights that are conceptually general.

A. Special Case of the Model with Binary Investment

In this special case of the model, investment is dichotomous. A worker decides to become qualified \((q)\) at cost \(k\), or remain unqualified \((u)\) at no cost. A qualified worker who is hired produces a fixed payoff \(\omega > 0\) for the firm who hires her, while an unqualified worker produces zero. As before, the cost distribution \(G(k)\) is the probability that a worker has investment cost no greater than \(k\); here, I additionally assume that \(G(0) = 0\) and that \(G(k)\) is continuously differentiable, with density \(g(k)\).

With binary investment, an employer’s prior belief is summarized by the fraction of workers it believes have invested. In addition, employers see a common signal \(\theta \in [0, 1]\), which in this case has CDF \(F_i(\theta)\) and PDF \(f_i(\theta)\) where \(i \in \{q, u\}\) and \(f_u(\theta) / f_q(\theta)\) is strictly decreasing in \(\theta\). In equilibrium, firms’ prior beliefs coincide with the true equilibrium probability \(\pi\) that a worker invests; and each firm offers to pay the worker a wage \(w(\theta|\pi)\) equal to her expected marginal product.

\[
\begin{align*}
\tau & = \text{a linear income tax,} \\
\bar{w} & = \pi \omega \text{ is the average wage. If she did not invest, she receives}
\end{align*}
\]

\[
\begin{align*}
w(\theta|\pi) & = \omega \times \frac{\pi f_q(\theta)}{\pi f_q(\theta) + (1 - \pi) f_u(\theta)} \\
\end{align*}
\]

The worker accepts her best offer, supplies a unit of labor and receives that wage. If she invested, she obtains utility \(v(\theta|\pi, \tau) - k = u((1 - \tau) w(\theta|\pi) + \tau \bar{w}) - k\), where \(\tau\) is a linear income tax, and \(\bar{w} = \pi \omega\) is the average wage. If she did not invest, she receives

\(^{53}\)The model with binary investment is similar to Moro and Norman (2004).
\[ v(\theta|\pi, \tau) = u((1 - \tau) w(\theta|\pi) + \tau w) \]. I assume that \( u(c) \) is strictly increasing, strictly concave and satisfies Inada conditions: \( \lim_{c \to 0} u'(c) = \infty \) and \( \lim_{c \to \infty} u'(c) = 0 \).

Integrating over \( \theta \), the expected utilities (gross of investment costs) for an investor (\( \bar{v}_q \)) and non-investor (\( \bar{v}_u \)) are given by equations 44 and 45.

\[
\begin{align*}
\bar{v}_q(\pi|\tau) &= \int_0^1 v(\theta|\pi, \tau) dF_q(\theta) - k \quad (44) \\
\bar{v}_u(\pi|\tau) &= \int_0^1 v(\theta|\pi, \tau) dF_u(\theta) \quad (45)
\end{align*}
\]

Since workers invest if their expected return is greater than their cost, this implies an investment rate of \( G(\beta(\pi|\tau)) \) where \( \beta(\pi|\tau) = \bar{v}_q(\pi|\tau) - \bar{v}_u(\pi|\tau) \).

The final requirement of equilibrium is that workers invest at a rate that coincides with employers’ beliefs. This is embodied in equation 46, which states that the fraction of investors must be equal to the fraction of workers that employers believe are qualified.

\[ \pi = G(\beta(\pi|\tau)) \quad (46) \]

For a given tax rate \( \tau \), equation 46 defines a fixed point as shown in Figure C1. An employer belief \( \pi \), combined with the tax \( \tau \), pins down the investment return and an investment rate, \( G(\beta(\pi|\tau)) \).

Any point on the 45 degree line constitutes an equilibrium, since employers’ beliefs are confirmed. At the extremes, either \( \pi = 0 \) or \( \pi = 1 \) ensure that there is no return to investment, since employers who are certain of a worker’s decision place no weight on the signal. There is thus always an equilibrium in which no workers invest, and all workers receive a zero wage.\(^{54}\) Proposition 6 provides sufficient conditions for there to be others. For example, the economy in Figure C1 has four equilibria: 0, \( E_1 \), \( E_2 \) and \( E_3 \).

**Proposition 6.** Assume that \( \phi(\theta) = f_u(\theta) / f_q(\theta) \) is continuous and strictly positive on \([0, 1] \). If there exists \( \pi \) such that \( G(\beta(\pi|\tau)) > \pi \) then there are multiple solutions to condition 46.

Intuitively, these conditions are satisfied if the returns to investment are high enough, as ensured by a large value of \( \omega \) or a low enough tax rate. In turn, this means there is some employer belief \( \pi \) such that the fraction of investors given that belief, \( G(\beta(\pi|\tau)) \), is higher than \( \pi \). Since \( G(\beta(1|\tau)) = 0 \), and the regularity assumptions ensure that \( G(\beta(\pi|\tau)) \) is continuous \( \pi \), this guarantees that there is a belief \( \pi^* > 0 \) such that \( \pi^* = G(\beta(\pi^*|\tau)) \).

**B. Optimal Taxation with Binary Investment**

\(^{54}\)Tweaking the assumptions so that \( G(0) > 0 \) eliminates the equilibrium with zero investment.
Figure C1: Equilibria and Taxation

(a) Determination of Equilibria $\tau$

(b) Equilibrium Set for Each Value of $\tau$

Figure notes. This figure shows an example economy with binary investment. In panel (a), the aggregate rate of investment implied by worker and firm optimization, $G(\beta(\pi))$, is plotted against the employer prior, $\pi$. Any intersection between this line and the 45 degree line is an equilibrium. The arrows show the direction in which each equilibrium moves as $\tau$ rises. Panel (b) shows the set of equilibria over a range of values of $\tau$. Pareto dominant equilibria are shown by the black line segments.

Tax policy can be analyzed in the same way as in the general model. Raising the linear tax $\tau$ causes $G(\beta(\pi|\tau))$ to shift down for every employer belief $\pi$. As a result, the location of an equilibrium falls if $G(\beta(\pi|\tau))$ crosses the 45 degree line from above, and rises if it crosses from below, as shown in panel (b) of Figure C1.

For simplicity, I assume that agents play the planner’s preferred equilibrium, which ensures that investment and welfare always increase as $\tau$ is lowered. The arguments that follow do not depend on this assumption. However, it provides a concrete equilibrium selection criterion that is especially compelling here because equilibria for a given tax rate are Pareto-ranked, with higher investment corresponding to higher welfare. In Figure C1, the black line traces out the Pareto-dominant equilibria.

Proposition 7. Assume that multiple values of $\pi$ satisfy equation 46 for a given tax rate $\tau$. Let $\pi_i$ and $\pi_j$ be two solutions. Welfare is higher for every worker under $\pi_i$ than $\pi_j$ if and only if $\pi_i > \pi_j$. Moreover, investment in the Pareto-dominant equilibrium increases as $\tau$ is lowered.

55The set of equilibria can alternatively be refined by requiring stability in the sense introduced in Appendix B. In this case, the dynamic adjustment process is: $\pi_{t+1} = G(\beta(\pi_t|\tau))$. Stability amounts to a requirement that the absolute value of the slope of $G(\beta(\pi|\tau))$ is less than one, which implies that investment falls when $\tau$ rises. In Figure C1, both the zero investment equilibrium and $E_2$ are unstable.
Next, to characterize optimal taxation, define $\varepsilon_z$ as the elasticity of average income with respect to the retention rate. Second, let $u_\theta'$ be the marginal utility of consumption of an individual who sends signal $\theta$ and therefore receives wage $w(\theta|\pi)$. Finally, let $\tilde{u}_\theta'$ be the same individual’s marginal utility relative to the average: i.e., $\tilde{u}_\theta' = u_\theta'/\bar{u}_\theta'$. For simplicity, I assume here that the planner’s social welfare function is linear, but additional concavity from the social welfare function does not change the analysis.

Proposition 8 provides a necessary condition for the optimality of $\tau$, in the same form as Propositions 2 and 3. As before, there is a trade-off between redistribution from high-wage to low-wage workers, a fiscal externality and a belief externality. Ignoring the belief externality, an optimal $\tau$ at which this condition holds would always be strictly positive. The belief externality $w_z$ provides an efficiency motive for intervention and pushes toward lower tax rates.

**Proposition 8.** Fix a value of $\tau$ and an investment rate $\pi^* (\tau) > 0$, which satisfies equation 46. If $g (\beta (\pi^* (\tau) | \tau)) \beta' (\pi^* (\tau) | \tau) \neq 1$ and $\tau$ is optimal, then the following condition holds:

$$\frac{\tau}{1 - \tau} = \frac{\bar{u}_\tau - \varepsilon_z \bar{w}_z}{\varepsilon_z} \tag{47}$$

where $\bar{u}_\tau = (1 - \pi) \int_0^1 \tilde{u}_\theta' [f_u (\theta) - f_q (\theta)] d\theta$, $\varepsilon_z$ is the elasticity of income to the retention rate $1 - \tau$, and $\bar{w}_z = \frac{1}{\omega} \int_0^1 \tilde{u}_\theta' \frac{\partial w (\theta | \pi)}{\partial \pi} \left[ \pi f_q (\theta) + (1 - \pi) f_u (\theta) \right] d\theta$ is the belief externality.

Proposition 8 parallels the results from the linear tax example (Proposition 2) and non-linear taxation (Proposition 3). The requirement that $g (\beta (\pi^* (\tau) | \tau)) \beta' (\pi^* (\tau) | \tau) \neq 1$ simply suffices to ensure the investment rate varies continuously with $\tau$ at the optimum, which is equivalent to invertibility of the Jacobian, $J_{f,f_x}$, discussed in Appendix B. Graphically, it amounts to a requirement that $G (\beta (\pi | \tau))$ is not tangent to the 45 degree line in Figure C1. If it were tangent, then it would imply an upward discontinuity in the equilibrium correspondence as at $\tau_B$ in Panel (b).

**C. LIMITATIONS OF THE FIRST ORDER APPROACH**

The model with binary investment provides a transparent and flexible platform to discuss complications that could lead to discontinuity at the optimum or prevent my necessary conditions from being sufficient for optimality. The first caveat is that condition 8 may hold at other points. For example, the planner’s optimal tax rate may be $A_1$ in panel (b) of Figure C1, but the first-order condition may also hold at $C$. This a natural limitation of the first-order approach, which is not specific to this model.

The second caveat is more interesting: in some economies, there may be an incentive for the planner to choose a tax rate that places the economy at a discontinuity. For example,
consider again panel (b) of Figure C1. By Proposition 8, we know that $B_1$ dominates $B_2$. The complication is that it is possible for social welfare to be increasing in $\tau$ as we approach $\tau_B$ from below and also as we approach $\tau_B$ from above, so that $\tau_B$ is the optimal tax rate. However, equation 47 does not hold at the discontinuity. This is not a violation of Proposition 8, since $g(\beta(\pi|\tau))\beta'(\pi|\tau) = 1$ at $B_1$. However, it highlights a conceptually important limitation of the first-order approach in this context.

D Multiple Groups and Self-fulfilling Disparities
(For Online Publication)

A possibility with multiple equilibria is that employers have different beliefs about members of distinct groups (e.g., black and white workers). Although this is ruled out if agents always play the planner’s preferred equilibrium and the groups are identical, asymmetric equilibria could well arise in reality. This is the classic case of self-fulfilling statistical discrimination, as analyzed by Arrow (1973), Coate and Loury (1993), and others. In this appendix, I discuss the implications of this for optimal taxation.

My first step is to adapt the model in Appendix C by dividing workers into an advantaged (A) group and a disadvantaged (D) group. Specifically, I assume that a worker is of type $A$ with probability $\lambda_A$ and of type $D$ with probability $\lambda_D = 1 - \lambda_A$. The two groups are identical in fundamentals. As in Appendix C, the planner is restricted to linear taxation. However, she can set a different tax rate $\tau_j$ for each group $j \in \{A, D\}$, and a lump sum transfer $T_{A \rightarrow D}$ from As to Ds. These three variables constitute a tax system $T$.

**Definition 3.** A tax system $T$ is a triple $(\tau_A, \tau_D, T_{A \rightarrow D})$, comprised of a marginal tax rate $\tau_j$ for each group combined with an intergroup transfer $T_{A \rightarrow D}$.

Equilibrium in the model with two distinct groups can be characterized as follows. First, net of investment costs, a worker of type $j$ with signal $\theta$ receives utility $v_j(\theta|\pi_j, T)$.

$$v_A(\theta|\pi_A, T) = u\left[(1 - \tau_A) \omega \frac{\pi_A f_q(\theta)}{\pi_A f_q(\theta) + (1 - \pi_A) f_u(\theta)} + \tau_A \pi_A \omega - \frac{T_{A \rightarrow B}}{\lambda_A}\right]$$

$$v_D(\theta|\pi_D, T) = u\left[(1 - \tau_D) \omega \frac{\pi_D f_q(\theta)}{\pi_D f_q(\theta) + (1 - \pi_D) f_u(\theta)} + \tau_D \pi_D \omega + \frac{T_{A \rightarrow D}}{\lambda_D}\right]$$

Gross of investment costs, a worker’s expected utility is thus $\overline{v}_q^j(\pi_j|T)$ if she invests, and $\overline{v}_u^j(\pi_j|T)$ if she does not.

$$\overline{v}_q^j(\pi_j|T) = \int_0^1 v_A(\theta|\pi_j, T) dF_q(\theta) \quad \overline{v}_u^j(\pi_j|T) = \int_0^1 v_B(\theta|\pi_j, T) dF_u(\theta)$$
The model remains otherwise unchanged from Appendix C. Workers invest if the return, \( \beta_j (\pi_j | T) = \overline{v}_q^j (\pi_j | T) - \overline{v}_u^j (\pi_j | T) \), is greater than their cost, implying an investment rate of \( G (\beta_j (\pi_j | T)) \). Equilibrium requires that \( \pi_j = G (\beta_j (\pi_j | T)) \), \( j \in \{ A, D \} \).

Unlike Appendix C, I do not assume that agents coordinate on the planner’s preferred equilibrium. Instead, I follow the approach of Section 4, which applies given any continuous selection of equilibria. Specifically, for any given tax schedule \( T \), let \( \pi (T) \) be the set of pairs \( (\pi_A, \pi_D) \) such that \( \pi_j (T) = G (\beta_j (\pi(T)|T)) \) for \( j \in \{ A, D \} \). The correspondence \( \pi (T) \) suffices to characterize the set of equilibria for each tax schedule. I define a selection by choosing one equilibrium pair \( \pi^\dagger (T) \) for each tax schedule from this set.

Optimal taxation is then similar to the case with one group. The planner values both groups equally, so welfare is the weighted average \( W = \lambda_A W_A + \lambda_D W_D \), where:

\[
W_j = \pi_j \overline{v}_q^j (\pi_j | T) + (1 - \pi_j) \overline{v}_u^j (\pi_j | T) - \int_0^{\tau_j} (\tau_j - \nu_j^u (\pi_j | T)) k dG_j (k).
\]

Within each group, the same perturbation arguments apply and the condition required for \( \tau_j \) to be optimal is unchanged. The only additional complication is the inter-group transfer, which is set so that the average marginal utility is the same for As and Ds.

**Proposition 9.** If \( \pi^\dagger (T) \) is locally continuous and \( T \) is optimal, the following conditions hold.

\[
\frac{\tau_j}{1 - \tau_j} = \frac{\overline{v}_{j,\tau} - \varepsilon_z^j \overline{w}_z^j}{\varepsilon_z^j} (48)
\]

\[
\int_\theta u'_{A,\theta} d F (\theta) = \int_\theta u'_{B,\theta} d F (\theta) (49)
\]

where \( \overline{v}_{j,\tau} = (1 - \pi_j) \int_0^1 \overline{u}_{j,\theta} [f_u (\theta) - f_q (\theta)] d \theta \), \( \varepsilon_z^j \) is the income elasticity of group \( j \), and \( \overline{w}_z^j = \frac{1}{\omega} \int_0^1 \overline{u}_{j,\theta} \frac{\partial w (\theta | \pi_j)}{\partial \pi_j} \left[ \pi_j f_q (\theta) + (1 - \pi_j) f_u (\theta) \right] d (\theta) \) is the belief externality.

To build intuition, consider the case in which \( T_{A\rightarrow D} \) is constrained to be zero and \( \pi^\dagger (T) \) selects equilibria that are symmetric in the sense that \( \pi_A = \pi_B \). This is always possible, because the groups are identical. The planner’s choice of \( \tau_j \) is then isomorphic to the model with a single group, so \( \tau_A = \tau_B \) and \( \pi_A = \pi_B \). Moreover, if condition 48 holds, equation 49 must as well. Starting from equal treatment (\( \tau_A = \tau_B \) and \( T_{A\rightarrow D} = 0 \)), there is therefore no first-order gain from slightly changing the tax system. This implies that the planner would not want to set \( T_{A\rightarrow D} \neq 0 \), even if she could. Intuitively, if the two groups are identical and equilibria are symmetric, there is no motive for the planner to choose a tax system that favors one group over the other.

In general, however, it is possible that \( \pi^\dagger (T) \) includes non-symmetric equilibria, which raises the possibility of “self-fulfilling” differences between groups. In this case, even
through groups $A$ and $D$ are \textit{ex ante} identical, it is not generally true that $\pi_A = \pi_B$ even at the planner’s optimal choice of $T$. The optimal $T$ may then involve different marginal tax rates for $A$ and $B$ workers, and an inter-group transfer.

Although Proposition 9 still holds in this non-symmetric case, the potential for self-fulfilling asymmetries raises the question of whether there are policies that can eliminate this problem. One possibility is for the planner to set a tax that conditions on the aggregate level of investment, which would always allow the planner to ensure Pareto efficiency. Alternatively, one could imagine a dynamic policy that transitions the economy from one equilibrium to another. For example, one could temporarily implement a very low tax rate and then ratchet it back up, ensuring convergence to a Pareto efficient equilibrium.

\section*{E Approximately Optimal Taxation}

(For Online Publication)

This appendix provides a way of calculating an approximately optimal tax schedule given only a few measurable statistics. Two general principles underlie the approach. First, I assume that a change in $T'(z)$ primarily causes individuals with income close to $z$ to respond. Second, I assume that the incidence of the belief externality falls on workers with similar welfare weight, labor supply and tax rate to those with income $z$.

Part E of Section 4 shows that the welfare impact of a wage change due to the belief externality is weighted by $\Omega(z, \tilde{\theta}) = \psi_z(z(\tilde{\theta}|\pi), [1 - T'(z(\tilde{\theta}|\pi))]) l(\tilde{\theta}|\pi)$. Using this, and letting $l(z)$ be the labor supply at income $z$, I define $\tilde{\Omega}(z, \tilde{\theta})$ as the difference between the weight on externalities at income $z(\tilde{\theta}|\pi, T)$ and the weight at income $z$.

$$ \Omega(z, \tilde{\theta}) = \psi_z(z(\tilde{\theta}|\pi, T)) [1 - T'(z(\tilde{\theta}|\pi, T))] l(\tilde{\theta}|\pi) - \psi_z(z) [1 - T'(z)] l(z) $$

The belief externality can then be rewritten as an approximation, plus a covariance bias.

$$ \text{BE}(z) = -d\tau dz \left\{ \psi_z(z) [1 - T'(z)] l(z) \left[ \int_{\Theta} \left( \frac{dw(\tilde{\theta}|\pi)}{d[1 - T'(z)]} \right) f(\tilde{\theta}) d\tilde{\theta} \right] \right\} + \int_{\Theta} \tilde{\Omega}(z, \tilde{\theta}) \left( \frac{dw(\tilde{\theta}|\pi)}{d[1 - T'(z)]} \right) f(\tilde{\theta}) d\tilde{\theta} \right\} $$

\text{Covariance bias}

Next, without loss of generality, I write the externality as a share of the average wage rise.

$$ \int_{\Theta} \frac{dw(\tilde{\theta}|\pi)}{d[1 - T'(z)]} f(\tilde{\theta}) d\tilde{\theta} = (1 - s(z)) \frac{d\pi}{d[1 - T'(z)]} $$

(51)
Bringing everything together, expression 18 is approximately zero if:

\[ \text{FE}(z) + \text{ME}(z) - (1 - s(z)) \psi_z(z) l(z) \left[ 1 - T'(z) \right] \frac{d \psi}{d \left[ 1 - T'(z) \right]} = 0. \]  

(52)

**Figure E1: Approximately Optimal Taxation**

*Figure notes.* This figure shows the results of the simulation described in Section I. The solid red line shows the optimal tax schedule, the dashed blue line shows the naïve schedule, and the dotted black line shows a schedule what would be accepted by a planner who implemented equation 52.

An advantage of this equation is that it facilitates assumptions about how the belief externality varies with income without finding corresponding distributional assumptions. As in Section 4, the correction term in equation 52 is larger if: (i) investment is more responsive; (ii) workers capture little of their return to investment; or (iii) a worker supplies a large amount of labor, faces a low tax rate, and receives substantial welfare weight.

Figure E1 shows the results when equation 52 is implemented in my simulated economy. The optimal and approximately optimal tax schedules are similar at lower levels of income, but the approximation deteriorates at higher levels of income where the true impact of the externality is more disperse. Starting from the naïve benchmark, 60 percent of the gains from optimal taxation are achieved via the approximation.

**F Unproductive Signaling**

(For Online Publication)

If the productivity of a worker depends directly on her type as well as her human capital investment, it is possible for investment to play an unproductive or ‘pure’ signaling role
as in Spence (1973). Investment returns then reflect both a genuine increase in skill, and partial revelation of innate ability. In general, the overall externality from investment may then be more positive or more negative than in the model without innate ability.\textsuperscript{56}

A. UNPRODUCTIVE SIGNALING: EXAMPLE WITH LINEAR TAXATION

I start with an extension of the example in Section 3, and then study the general case. Productivity, \( q = n^\alpha h^{1-\alpha} \), is a Cobb-Douglas combination of human capital \( h \) and innate ability \( n \). Human capital, \( h = x^\beta \), is attained via investment, \( x \). Inherent ability is negatively related to a worker’s investment cost: \( n = 1/k \). Finally, the ability distribution and the conditional signal distribution are log-normal.

\[
\ln n \sim \mathcal{LN} \left( \ln \mu_n - \frac{\sigma_n^2}{2}, \sigma_n^2 \right) \quad \ln \theta = \ln x + \ln \xi \quad \ln \xi \sim \mathcal{N} \left( 0, \sigma_\xi^2 \right)
\]

There is again an equilibrium in which income and productivity are log-normally distributed. The elasticities of productivity and income are functions of the labor supply elasticity, \( \varepsilon_l \), the production function elasticity, \( \beta \), and the importance of innate ability, \( \alpha \).

**Proposition 10.** For any tax rate \( \tau \), there is an equilibrium in which productivity and income are log-normally distributed. Assuming this equilibrium is played, the elasticities of productivity and investment with respect \( 1-\tau \) are as follows.

\[
\varepsilon_q = \frac{\beta (1-\alpha) (1+\varepsilon_l)}{1-\beta (1-\alpha) (1+\varepsilon_l)} \quad \varepsilon_z = \frac{\varepsilon_l + \beta (1-\alpha) (1+\varepsilon_l)}{1-\beta (1-\alpha) (1+\varepsilon_l)}
\]

This example nests the version in Section 3 in which investment is purely productive. When \( \alpha = 0 \) so that \( q = h \), the two elasticities \( \varepsilon_q \) and \( \varepsilon_z \) collapse to that case, and equation 53 collapses to equation 11. When \( \alpha = 1 \) so that \( q = n \), productivity does not respond to taxation, and the income elasticity collapses to the elasticity of labor supply.

The first-order condition for the optimal tax is given by Proposition 11. It features a second externality correction, \( 1+s\alpha (1+\varepsilon_l) \), which pushes toward higher rather than lower taxes. Intuitively, there is no social benefit from the part of the private return to investment that comes from signaling innate ability, which implies that this return comes at the expense of other workers. The logic here is similar to the rent transfer effect in Section 4. Holding fixed the decisions of others, a worker who invests more hurts other

\textsuperscript{56}The empirical importance of unproductive signaling is hard to assess. For formal education, evidence from school reforms demonstrate substantial productive effects (Meghir and Palme 2005, Aakvik, Salvanes and Vaage 2010, Oreopoulos 2006), but there is also evidence to suggest a role for pure signaling (Lang and Kropp 1986, Bedard 2001, Aryal et al. 2020). See Lange and Topel (2006) for a discussion.
workers, because she becomes more likely to be pooled by employers with workers who have higher productivity than herself, thereby lowering the wages of those other workers.

Proposition 11. Assume that the log-normal equilibrium described in Proposition 10 is played. Then the first-order condition for the optimal linear tax $\tau^*$ is:

$$\frac{\tau^*}{1 - \tau^*} = \frac{1 - \gamma}{\varepsilon_z} \left[ \frac{1 + (1 - s) \varepsilon_q}{1 + s \alpha (1 + \varepsilon_l)} \right]$$

where $s = \frac{\sigma_x^2}{\sigma_x^2 + \sigma_q^2}$ and $\gamma = E_n \left( \psi_n \sigma_n \frac{\sigma_n}{\sigma_q} \right)$.

Since imperfect employer information now generates two opposite-signed externalities, there are combinations of $\alpha$ and $s$ that cause them to perfectly offset each other.

The condition on the left states that the social and private benefits of investment are aligned. The one on the right states that the unproductive component of the private return is equal in magnitude to the part of the productive component that is not captured by the individual. If these conditions hold, condition 53 collapses to the standard optimal tax formula. Any other parameter values imply a correction on efficiency grounds.

As these equations show, noisier employer information implies a smaller private benefit of investment for a given social benefit. Specifically, lower $s$ dampens the signaling externality but strengthens the learning externality. In this sense, evidence of residual employer uncertainty (Lange 2007, Kahn and Lange 2014) suggests a more positive externality, and implies lower optimal tax rates than if employers had better information.

B. Unproductive Signaling: General Case with Observable Investment

I next move beyond the simple example, and extend the general model outlined in Section 2 to allow for unproductive signaling. However, I start with the simpler case in which investment is perfectly observable. This entails replacing the production function with $q = Q (x, k)$, so that productivity is a direct function of the worker’s type. Employers observe productivity, $x$, but do not observe productivity, $q$.

This results in a deterministic equilibrium mapping from investment to wages, $w (x)$. Taking this as given, the worker’s investment problem is:

$$\max_{x \in \mathbb{R}^+} v (w (x) | T) - k x$$

(54)
where:

\[ v(w(x)|T) = \max_{l \in \mathbb{R}_+} u(w(x)l - T(w(x)l), l). \]  

(55)

The solutions to problem 54 for each cost type jointly define a second mapping, \( x(k) \), from costs to investment levels.

To simplify the analysis, I assume \( w(x) \) is one-to-one. Given this, I provide conditions in Part C that guarantee \( x(k) \) and \( w(x) \) are differentiable, which ensures that the investment choice for a worker with cost \( k \) is characterized by a first-order condition:

\[ u_c(z(k) - T(z(k)), l(k)) \left[ 1 - T'(z(k)) \right] l(k) w'(x(k)) = k \]  

(56)

where \( l(k) \) is the level of labor supply that solves problem 55, and \( z(k) = w(x(k))l(k) \) is the equilibrium income of a worker with cost \( k \).

This relationship between innate ability and investment drives a wedge between the private and social returns, which I refer to as the unproductive component.

\[ \frac{Q_k(x(k), k)}{x'(k)} = w'(x(k)) - \frac{Q_x(x(k), k)}{x'(k)} \]  

(57)

If \( Q_k(x(k), k) < 0 \) so that costs are positively related to ability, there is a positive externality from investment: an individual who invests more makes others look better because she has higher productivity than those who invest at that level in equilibrium. Conversely, if \( Q_k(x(k), k) < 0 \), there is a negative externality from investment.

These results provide a foundation for policy analysis that mirrors Section 4. Specifically, consider again a perturbation that raises the marginal tax rate by \( d\tau \) on income between \( z \) and \( z + dz \), while raising the intercept of the tax schedule to ensure that the resource constraint still holds. A different but related form of belief externality arises.

\[ \text{BE}(z) = -d\tau d\int_K \psi(k) \left[ 1 - T'(z(k)) \right] l(k) \frac{dx(k)}{d[1 - T'(z)]} \left[ w'(x(k)) - Q_x(x(k), k) \right] dG(k) \]

This equation for \( \text{BE}(z) \) can again be written in terms of the observable income distribution, and combined with the fiscal externality and mechanical effect to obtain a necessary condition for optimality of the tax system:

\[ \text{FE}(z) + \text{ME}(z) + \int_Z \tilde{z} \psi(\tilde{z}) \left( 1 - T'(\tilde{z}) \right) \frac{1}{1 - T'(z)} \left[ \epsilon_{x}(\tilde{z}) \right] \left[ \epsilon_{w}(\tilde{z}) - \epsilon_{x}(\tilde{z}) \right] dH(\tilde{z}) = 0 \]  

(58)

where \( \tilde{w}(\tilde{z}) \) and \( \tilde{x}(\tilde{z}) \) are the wages and investment levels of a worker with income \( \tilde{z} \), and
the elasticities are defined as follows.

\[
\begin{align*}
\varepsilon_{\text{Private}}^x (\hat{w} (\hat{x}), \hat{x}) &= w' (x (k)) \frac{x (k)}{w (k)} \\
\varepsilon_{\text{Social}}^x (\hat{w} (\hat{x}), \hat{x}) &= Q_x (x (k), k) \frac{x (k)}{w (k)} \\
\varepsilon_{\hat{x} (\hat{z}), 1-T' (\hat{z})} &= \frac{dx (\hat{z})}{d[1-T' (\hat{z})]} \frac{1-T' (\hat{z})}{x (\hat{z})}
\end{align*}
\]

Note the similarity between expression 18 and equation 58. This is not coincidental: as before, employer inference causes misalignment between the private and social returns to investment, and the resulting externality enters social welfare in the same way.

C. DIFFERENTIABILITY OF \(w(x)\) AND \(x(k)\)

I next provide conditions under which \(w(x)\) and \(x(k)\) are differentiable in Part B above. As in Section 4, I assume that problem 55 is strictly concave given a wage \(w = w(x)\) so that the labor supply choice can be characterized by a first-order condition (equation 59):

\[
w u_c (wl^* (w) - T (wl^* (w)), l^* (w)) \left[1 - T' (wl^* (w))\right] + u_t (wl^* (w) - T (wl^* (w)), l^* (w)) = 0
\]

where \(l^* (w) = \arg\max_{l \in \mathbb{R}_+} u(wl - T(wl), l)\).

Next, I define \(\hat{v} (x) = v(w(x) | T)\), and let \(x_{FB} (k) = \arg\max_x v(Q(x, k) | T) - kx\) be the investment level chosen by an agent with cost \(k\) in the equivalent problem with perfect employer information. Using these definitions, I adopt three assumptions regarding problem 54, which can be viewed as restrictions on the investment technology, \(Q(x, k)\).

**Assumption 5.** The solution to the first best contracting problem, \(x_{FB} (k)\), is unique for all \(k\).

**Assumption 6.** For all \(k \in K\), \(\hat{v} (x)\) is strictly concave around \(x_{FB} (k)\).

**Assumption 7.** \(\exists \kappa > 0\) such that \(\hat{v}'' (x) \geq 0 \Rightarrow \hat{v}' (x) > \kappa\) for all \((k, x) \in K \times \mathbb{R}_+\).

A sufficient condition for assumption 5 to hold is that the first best contracting problem is strictly concave, which is always true given sufficient concavity of the investment technology. Assumption 6 simply states that problem 54 is locally strictly concave around the first-best investment choice, while assumption 7 is a global equivalent that is weaker than strict concavity but stronger than strict quasi-concavity.

Assumptions 5, 6 and 7 jointly ensure that \(x(k)\) is differentiable for all \(k \in K\) (see Mailath and von Thadden 2013), which in turn implies that \(w(x)\) is differentiable and that the following condition holds for all \(k\):

\[
u_c (z (k) - T (z (k)), l (k)) \left[1 - T' (z (k))\right] l (k) w' (x (k)) = k
\]

where \(l (k) = l^* (w(x (k)))\) and \(z (k) = w (x (k)) l (k)\).
D. UNPRODUCTIVE SIGNALING: IMPERFECTLY OBSERVABLE INVESTMENT

My final step is to consider the general case in which investment is unobservable. The remaining difference from Section 2 is that employers now observe a noisy signal of investment rather than productivity. Specifically, \( \theta \in \Theta \subseteq \mathbb{R}_+ \) has conditional density \( f(\theta|x) \) twice differentiable in \( x \), and full support for all \( x \). As before, it satisfies the monotone likelihood ratio property: \( \frac{\partial}{\partial \theta} \left( \frac{f(\theta|x_H)}{f(\theta|x_L)} \right) > 0 \) for all \( x_H > x_L \). Otherwise, I adopt all the assumptions from Section 2.

The equation for the belief externality, \( BE(z) \), remains very similar to Section 4. There remain distinct productivity and rent transfer effects, with the change in the equilibrium wage given signal realization \( \bar{\theta} \) given by equation 61.

\[
\frac{dw(\bar{\theta}|\pi)}{d[1 - T'(z)]} f(\bar{\theta}) = \int_K \left[ \frac{dx(k|\pi, T)}{d[1 - T'(z)]} \right] \left[ Q_x(x(k|\pi, T), k) f(\bar{\theta}|x(k|\pi, T)) \right. \\
+ \left. \left[ Q(x(k|\pi, T), k) - E(q|\bar{\theta}, \pi) \right] \left( \frac{\partial f(\bar{\theta}|x)}{\partial x} \bigg|_{x=x(k|\pi, T)} \right) \right] dG(k)
\]

However, there are important differences in the interpretation of these two effects. First, the productivity effect may be small or even entirely absent if investment costs are negatively correlated with innate ability. For example, an extreme possibility is that \( q = Q(k) \) so that productivity is unaffected by investment. In this case, the productivity effect is zero and investment returns must come entirely from unproductive signaling of one’s ability. The private gain from investment is thus fully offset by negative impacts on the wages of other workers. In this extreme case, the planner would set higher rather than lower optimal taxes, given the same mechanical effect and fiscal externality.

A second possibility is that investment costs are positively rather than negatively related to ability, which is possible providing that investment also raises productivity. The rent transfer effect then becomes less negative, and may even be positive, since a worker who considers increasing her investment has higher innate ability than those who invest at that new level in equilibrium. In this case, the “unproductive” component of the return reinforces rather than offsets the positive learning externality, and provides still further motivation to lower marginal tax rates and encourage investment.

G Proofs and Derivations
(For Online Publication)

Proof of Lemma 1. Firm beliefs about the distribution of productivity in the population
must be confirmed in equilibrium and identical across firms. Let \( \pi \) denote the equilibrium set of beliefs. Firm \( j \)'s expectation of the worker’s productivity is \( E [q|\theta, \pi, A_j = 1] \geq 0 \). Next, let \( \tilde{u}(w_j) = u(w_j l^*(w_j) - T(w_j l^*(w_j) , l^*(w_j)) \) represent the utility that the worker receives from accepting wage \( w_j \) and supplying labor optimally.

Suppose that some firm \( j \) makes strictly positive expected profits given its wage offer \( w_j \). It must then be the case that \( \tilde{u}(w_j) \geq \tilde{u}(w_k) \) for all wages \( w_k \) offered by other firms. There are several cases to consider, each of which lead to a contradiction.

**Case 1:** \( \tilde{u}(w_j) > \tilde{u}(w_k) \) for some \( w_k \).

In this case, firm \( k \) initially earns zero expected profit, since no workers accept its offer. However, it can offer a wage slightly higher than \( w_j \). It then attracts the worker with probability one and earns strictly positive profits. This is a profitable deviation.

**Case 2:** \( \tilde{u}(w_j) = \tilde{u}(w_k) \) for all \( w_k \), and \( P_{k,\theta} \leq 0 \) for some \( k \).

If any firm makes weakly negative profits, then the same deviation as Case 1 applies.

**Case 3:** \( \tilde{u}(w_j) = \tilde{u}(w_k) \) and \( P_{k,\theta} > 0 \) for all \( k \).

Since the worker always accepts an offer, \( E [q|\theta, \pi, A_j = 1] \) is bounded weakly below \( E [q|\theta, \pi] \) for at least one firm. This firm’s expected profit is bounded below \( \overline{P}_{\text{MAX}} \).

\[
\overline{P}_{\text{MAX}} = \max_w [E[q|\theta, \pi] - w] l^*(w) \text{ s.t. } u(wl^*(w) - T(wl^*(w)) , l^*(w)) \geq u(T(0) , 0)
\]

The assumptions on the worker’s utility function ensure that this yields finite labor supply for any finite \( E[q|\theta, \pi] \). Since \( w_j \) is greater than zero and \( E[q|\theta, \pi] \) is finite, \( \overline{P}_{\text{MAX}} \) is also bounded. Finally, this firm can strictly increase its profit by raising \( w_j \) slightly and attracting the worker with probability one.

Since every case in which a firm makes a strictly positive expected profit implies a profitable deviation, and all firms can obtain zero expected profit by offering a zero wage, it must be true that every firm makes zero expected profit. Finally, the wage, \( w \), must be the same at every firm who hires the worker with positive probability. We have therefore established that \( [E[q|\theta, \pi] - w] l^*(w) = 0 \), which is only satisfied if \( w = E[q|\theta, \pi] \). \( \square \)

**Proof of Proposition 1.** Assume – subject to verification – that investment is distributed log-normally as hypothesized.

\[
\ln q_i \sim \mathcal{N}\left(\ln \mu_q - \frac{\sigma_q^2}{2}, \sigma_q^2\right)
\]
Given this, employers face a log-normal signal extraction problem. The expectation of log-productivity is as follows.

\[ E[\ln q|\theta] = \left( \frac{\sigma_q^2}{\sigma_q^2 + \sigma_\xi^2} \right) \ln \theta + \left( \frac{\sigma_\xi^2}{\sigma_q^2 + \sigma_\xi^2} \right) \left( \ln \mu_q - \frac{\sigma_q^2}{2} \right) \]

\[ = \left( \frac{\sigma_q^2}{\sigma_q^2 + \sigma_\xi^2} \right) \ln q + \left( \frac{\sigma_\xi^2}{\sigma_q^2 + \sigma_\xi^2} \right) \left( \ln \mu_q - \frac{\sigma_q^2}{2} \right) + \left( \frac{\sigma_\xi^2}{\sigma_q^2 + \sigma_\xi^2} \right) \ln \xi \]

Since employers offer workers their expected marginal product, the after-tax wage is:

\[ \ln [(1 - \tau) w] = \left( \frac{\sigma_q^2}{\sigma_q^2 + \sigma_\xi^2} \right) \ln q + \left( \frac{\sigma_\xi^2}{\sigma_q^2 + \sigma_\xi^2} \right) \ln \mu_q + \left( \frac{\sigma_\xi^2}{\sigma_q^2 + \sigma_\xi^2} \right) \ln \xi + \ln (1 - \tau). \]

Exponentiating, we obtain the level of wages: \( w = q^s \mu_q^{1-s} \xi^s \), where \( s = \sigma_\xi^2 / (\sigma_q^2 + \sigma_\xi^2) \). Given this wage, labor supply is \( l = (1 - \tau)^{1+\varepsilon_l} w^{1+\varepsilon_l} \), which implies an after-tax income of:

\[ (1 - \tau) z = (1 - \tau) w l = (1 - \tau)^{1+\varepsilon_l} w^{1+\varepsilon_l} = [(1 - \tau) q^s \mu_q^{1-s} \xi^s]^{1+\varepsilon_l}. \]

Next, since \( q = Q(x) = x^\beta \) and costs are linear, expected utility is as follows.

\[ \left( (1 - \tau)^{1+\varepsilon_l} \mu_q^{(1-s)(1+\varepsilon_l)} \right) E \left[ \xi^{s(1+\varepsilon_l)} \right] \frac{x^{\beta s(1+\varepsilon_l)}}{1+\varepsilon_l} - kx + \tau z \]

Since I assume that \( \beta s (1 + \varepsilon_l) < 1 \), we can differentiate to find the agent’s choice of \( q \).

\[ q = \left[ \frac{\beta s \left( (1 - \tau)^{1+\varepsilon_l} \mu_q^{(1-s)(1+\varepsilon_l)} \right) E \left[ \xi^{s(1+\varepsilon_l)} \right]}{k} \right]^{1/1-\beta s (1+\varepsilon_l)} \]

Then, since \( \ln q \) is the sum of two normally distributed variables and a constant term, \( q \) is itself log-normally distributed. Specifically, it has the following distribution.

\[ \ln q \sim \mathcal{N} \left( \frac{\beta}{1 - \beta s (1 + \varepsilon_l)} \ln \beta + \frac{\beta}{1 - \beta s (1 + \varepsilon_l)} \ln s + \frac{\beta (1 + \varepsilon_l)}{1 - \beta s (1 + \varepsilon_l)} \ln (1 - \tau) + (1 - s) \frac{\beta (1 + \varepsilon_l)}{1 - \beta s (1 + \varepsilon_l)} \ln \mu_q + \frac{\beta}{1 - \beta s (1 + \varepsilon_l)} \ln E \left[ \xi^{s(1+\varepsilon_l)} \right] - \frac{\beta}{1 - \beta s (1 + \varepsilon_l)} \left( \ln \mu_k - \frac{\sigma_k^2}{2} \right) \cdot \left( \frac{\beta}{1 - \beta s (1 + \varepsilon_l)} \right)^2 \sigma_k^2 \right) \]

Finally, we can obtain expressions for \( \mu_q \) and \( \sigma_q^2 \) by matching coefficients.
Equation 62 implicitly pins down $\sigma_q^2$ in terms of $\sigma_k^2$, $\beta$, $\varepsilon_l$ and $\sigma_\xi^2$. It is independent of $\mu_k$.

In turn, equation 63 characterizes $\mu_q$ as a function of the same set of parameters plus $\mu_k$.

The elasticity of $\mu_q$ with respect to $\mu_k$ is $-\beta / [1 - \beta (1 + \varepsilon_l)]$.

**Proof of Lemma 2.** There are two effects on $q$ of increasing the retention rate $1 - \tau$: a direct effect, and an effect via average productivity. Combining these yields the total elasticity.

$$
\sigma_q = \frac{dq}{d(1-\tau)} \times \frac{1 - \tau}{q} = \left[ \frac{\partial q}{\partial (1-\tau)} + \frac{\partial q}{\partial \mu_q} \frac{d\mu_q}{d(1-\tau)} \right] \frac{1 - \tau}{q} \mu_k \left( \frac{1}{1 - s} \right) \left( 1 + \varepsilon_l \right) \left( \frac{1 - \beta (1 + \varepsilon_l)}{1 - \beta (1 + \varepsilon_l)} \right)
$$

Similarly, we can derive the elasticity of income $z$ to the retention rate.

$$
\sigma_z = \frac{dz}{d(1-\tau)} \times \frac{1 - \tau}{z} = \left[ \frac{\partial z}{\partial (1-\tau)} + \frac{\partial z}{\partial \mu_q} \frac{d\mu_q}{d(1-\tau)} + \frac{\partial z_i}{\partial \mu_q} \frac{d\mu_q}{d(1-\tau)} \right] \frac{1 - \tau}{z} \varepsilon_l + \beta (1 + \varepsilon_l)
$$

**Proof of Proposition 2.** The utility of a worker with noise realization $\xi$ and cost $k$ is:

$$
v = \frac{[(1 - \tau) q^s \mu_q^{1 - s} \xi^s]^{1 + \varepsilon_l}}{1 + \varepsilon_l} - kx + \tau \bar{z}
$$

where $x$ is chosen optimally according to the following first-order condition.

$$
k = \beta s \left( (1 - \tau) ^{1 + \varepsilon_l} \mu_q^{(1 - s)(1 + \varepsilon_l)} \right) E \left[ \xi^{s(1 + \varepsilon_l)} \right] x^{\beta s (1 + \varepsilon_l) - 1}
$$
Taking the expectation over $\xi$, the expected utility for an individual with cost $k$ is:

$$\left[\frac{1 - \beta s (1 + \varepsilon_l)}{1 + \varepsilon_l}\right] \left( (1 - \tau)^{1+\varepsilon_l} \mu_q (1-s)(1+\varepsilon_l) \right) E\left[\xi^{s(1+\varepsilon_l)}\right] q^{s(1+\varepsilon_l)} + \tau \overline{\varepsilon}$$

Then, substituting in the optimal choice of $q$, and weighting by the worker’s welfare weight $\psi_k$, we get expected welfare in terms of $\mu_q$ and $\xi$.

$$E_{\xi} [\psi_k v_k, \xi | k] = \psi_k \left[\frac{1 - \beta s (1 + \varepsilon_l)}{1 + \varepsilon_l}\right] \left( (1 - \tau)^{1+\varepsilon_l} \mu_q (1-s)(1+\varepsilon_l) \right) \left[1 + \frac{\beta s (1+\varepsilon_l)}{1-\beta s (1+\varepsilon_l)}\right]$$

$$\times \left( \frac{\beta s (1+\varepsilon_l)}{k} \right)^{\frac{1 - \beta s (1+\varepsilon_l)}{1-\beta s (1+\varepsilon_l)}} \left\{ E\left[\xi^{s(1+\varepsilon_l)}\right]\right\}^{\frac{1}{1-\beta s (1+\varepsilon_l)}} + \psi_k \tau \overline{\varepsilon}$$

$$= (1 - \tau) \psi_k \overline{\varepsilon} \left[\frac{1 - \beta s (1 + \varepsilon_l)}{1 + \varepsilon_l}\right] + \psi_k \tau \overline{\varepsilon}$$

Finally, we can integrate over cost realizations to obtain average welfare.

$$E [\psi_k v_k, \xi] = (1 - \tau) E [\psi_k \overline{\varepsilon} k] \left[\frac{1 - \beta s (1 + \varepsilon_l)}{1 + \varepsilon_l}\right] + \tau \overline{\overline{\varepsilon}}$$

Building on this result, there are three effects from raising the retention rate. First, there is a fiscal externality from the change in average income, $\overline{\varepsilon}$.

$$FE = \tau \overline{\overline{\varepsilon}} \overline{\varepsilon} \left[\frac{1 - \beta s (1 + \varepsilon_l)}{1 + \varepsilon_l}\right]$$

Second, welfare rises due to the externality via employer beliefs. Specifically, differentiating with respect to $\mu_q$ and aggregating over $k$, the gain in social welfare is as follows.

$$BE = (1 - s) E_k (\psi_k \overline{\varepsilon} k) \varepsilon_q$$

Finally, there is a mechanical welfare loss due to the transfer from the average worker to high-income workers:

$$ME = E_k (\psi_k \overline{\varepsilon} k) - \overline{\psi} \overline{\varepsilon}$$

Summing the three effects we obtain an expression for the total welfare gain.

$$FE + ME + BE = \frac{\tau}{1 - \tau} \overline{\varepsilon} \overline{\varepsilon} \overline{\varepsilon} + E_k (\psi_k \overline{\varepsilon} k) \left[1 + (1 - s) \varepsilon_q\right] \overline{\varepsilon} - \overline{\psi} \overline{\varepsilon}$$

Then setting this to zero yields the first-order condition shown in the proposition. \( \Box \)
Proof of Proposition 3. The objective of the social planner is to maximize welfare $W(T)$ subject to the four constraints of Problem 5. This problem is restated here for convenience.

$$\max_T W(T) = \int_K W(V(k, T)) \, dG(k)$$

where:

$$V(k, T) = \int_{\Theta} (v(\theta|\pi, T) - k x(k, \pi, T)) \, f(\theta, q(k|\pi, T)) \, d\theta$$

subject to:

$$x(k|\pi, T) \in \arg\max \ \hat{x} \in \mathbb{R}_+ \ \int_{\Theta} v(\theta|\pi, T) f(\theta|Q(\hat{x})) \, d\theta - k \hat{x}$$

$$l(\theta|\pi, T) \in \arg\max \ l(\theta|\pi) \int_{\Theta} u(\theta|\pi) \, f(\theta|Q(l)) \, d\theta$$

$$w(\theta|\pi) = \frac{\int_K q(k|\pi, T) \, f(\theta|q(k|\pi, T)) \, dG(k)}{\int_K f(\theta|q(k|\pi, T)) \, dG(k)}$$

$$R = \int_{\Theta} T(z(\theta|\pi, T)) \, f(\theta) \, d\theta$$

For ease of discussion, it will also be helpful to recall that $v(\theta|\pi, T)$ can be expanded and written as a function of a worker’s wage, labor supply and tax liability.

$$v(\theta|\pi, T) = u(w(\theta|\pi) \, l(\theta|\pi, T) - T(w(\theta|\pi) \, l(\theta|\pi, T)), l(\theta|\pi, T))$$ (64)

A perturbation to $T$ as described has three effects that I will consider in turn. First, there is a welfare loss ($WL$) from taking money from individuals with income higher than $z$.

$$WL = -d\tau dz \left\{ \int_{\Theta(z|\pi, T)} u_c(\theta) \int_K \psi(k) dG(k|\theta) f(\theta) \, d\theta \right\}$$ (65)

Since the revenue raised is returned to all individuals equally via an increase in the intercept of the tax schedule, it is worth $\lambda$ per dollar in terms of social welfare, where:

$$\lambda = \int_{\Theta} u_c(\theta) \int_K \psi(k) dG(k|\theta) f(\theta) \, d\theta$$ (66)

Multiplying by the amount of revenue raised, the welfare gain ($WG$) from this transfer is:

$$WG = d\tau dz \left\{ \int_{\Theta(z|\pi, T)} f(\theta) \, d\theta \right\} \lambda.$$ (67)

Summing $WL$ and $WG$, then dividing by $\lambda$ yields the mechanical gain in welfare, $ME(z)$. The second effect to consider is the fiscal externality, $FE(z)$, which arises when indi-
ividuals re-optimize. The value of the fiscal externality can be obtained by differentiating the resource constraint, yielding the impact on government revenue from re-optimization.

Since the focal selection \((E (T), T)\) is assumed to be locally continuously differentiable with respect to \(T, l (\theta|\pi, T)\) and \(x (k|\pi, T)\) respond continuously to the perturbation. Next, since \(x (k|\pi, T)\) responds continuously and \(Q\) is differentiable, so does \(q (k|\pi, T) = Q (x (k|\pi, T))\). Finally, since \(f (\theta) = \int K f (\theta|q (k|\pi, T)) dG(k)\) is continuous in \(q (k|\pi, T)\), \(f (\theta)\) responds continuously. In turn, this implies that \(w (\theta|\pi)\) responds continuously. The change in income given a signal realization \(\theta\) can therefore be written as follows.

\[
-dz(\theta|\pi, T) \frac{d}{d[1 - T'(z)]} = -w (\theta|\pi, T) \frac{dl (\theta|\pi, T)}{d[1 - T'(z)]} - l (\theta|\pi, T) \frac{dw (\theta|\pi, T)}{d[1 - T'(z)]}
\]

These results allow the fiscal externality to be written as a combination of the effects of changes in \(z(\theta|\pi, T)\) and \(f(\theta)\), capturing the effect on government revenue from both investment and labor supply decisions. After dividing through by \(\lambda\), the total fiscal externality is as follows.

\[
FE (z) = -d\tau dz \int_\Theta \left\{ T'(z(\tilde{\theta}|\pi)) \left( \frac{dz(\tilde{\theta}|\pi, T)}{d[1 - T'(z)]} \right) f(\tilde{\theta}) - T(z(\tilde{\theta}|\pi, T)) \frac{df(\tilde{\theta})}{d[1 - T'(z)]} \right\} d\tilde{\theta}
\]

The final effect of taxation is the effect on individual utility of changing wages in response to shifts in the distribution of productivity (BE). Since individuals take the wage paid given any signal realization as fixed, they ignore this effect. Differentiating the belief consistency constraint, the effect of a rise in individual \(k\)'s productivity on the wage of a worker with signal realization \(\theta\) is as follows.

\[
\frac{dw (\theta|\pi)}{dq (k|\pi, T)} = \frac{f(\theta, q(k|\pi, T))}{f(\theta)} + \left( \frac{\partial f(\theta, q)}{\partial q} \right) \left[ q (k|\pi, T) - E(q|\theta, \pi) \right]
\]

Applying the envelope theorem and again dividing by \(\lambda\), the effect of this wage change on social welfare is simply scaled by the affected worker's labor supply, retention rate and the average welfare weight of an individual with signal realization \(\theta\).

\[
\frac{dw(\tilde{\theta}|\pi)}{dq(k|\pi, T)} \psi_z(z(\tilde{\theta}|\pi, T)) \left[ 1 - T'(z(\tilde{\theta}|\pi, T)) \right] l(\tilde{\theta}|\pi)
\]

To obtain the total belief externality shown in the main text, we then integrate over the distributions of \(\theta\) and \(k\).

These three effects jointly capture the total change in welfare from a perturbation, since
the effects of individuals’ re-optimization on their own welfare are second-order. Thus, given any continuous selection, if \( \text{FE} + \text{BE} + \text{ME} \neq 0 \), welfare increases in response either to an arbitrarily small positive perturbation or an equivalent negative perturbation. Except at a discontinuity at which \( \text{ME}, \text{FE} \) and \( \text{BE} \) are not defined, a necessary condition for an optimum is therefore that the sum of the three effects is zero.

\[ \square \]

Proof of Proposition 10. Assume – subject to verification – that productivity and investment are log-normally distributed.

\[ q \sim \mathcal{LN} \left( \ln \mu_q - \frac{\sigma_q^2}{2}, \sigma_q^2 \right) \]

Next, suppose the relationship between productivity and investment can be written as:

\[ \ln q = \ln A + B \ln x \]

where \( A \) and \( B \) are scalars that will be found by matching coefficients. This allows the signal to be written as a linear combination of productivity \( q \) and noise \( \xi \).

\[ \ln \theta = \left( \frac{1}{B} \right) \ln q - \left( \frac{1}{B} \right) \ln A + \ln \xi \]

For convenience, define \( \ln \tilde{\xi} = B \ln \xi \) and let \( \ln \tilde{\theta} \) be the following linear transformation of the signal.

\[ \ln \tilde{\theta} = B \ln \theta + \ln A = \ln q + B \ln \xi = \ln q + \ln \tilde{\xi} \]

The expected log-marginal product of an individual follows from the fact that the employer faces a standard normal signal extraction problem:

\[ E \left[ \ln q | \tilde{\theta} \right] = s \ln \tilde{\theta} + (1 - s) \left( \ln \mu_q - \frac{\sigma_q^2}{2} \right) \]

where \( s = \sigma_q^2 / (\sigma_q^2 + \sigma_x^2) = \sigma_x^2 / (\sigma_q^2 + \sigma_x^2) \). A worker’s expected level of productivity is therefore a geometric weighted average of \( A, x, \xi \) and \( \mu_q \).

\[ w = \tilde{\theta}^s \mu_q^{1-s} = A^s x^s B \xi^s B \mu_q^{1-s} \]

Optimal labor supply is \( l = (1 - \tau)^{\varepsilon_l} w^{\varepsilon_l} \), which means that after tax income is:

\[ (1 - \tau) z = (1 - \tau)^{1+\varepsilon_l} w^{1+\varepsilon_l} \]
\[ (1 - \tau)^{1+\varepsilon_l} \left[ A^s x^s B \xi^s B \mu^1_{1-s} \right]^{1+\varepsilon_l}. \]

In turn, this implies a value of expected utility for any investment level.

\[ v = \left[ A^s (1 - \tau) \mu^1_{q} \right]^{1+\varepsilon_l} E \left[ \xi^{s B(1+\varepsilon_l)} \right] \frac{x^{s B(1+\varepsilon_l)}}{1+\varepsilon_l} - k x + \tau z \]

Assuming again that \( \beta s (1 + \varepsilon_l) < 1 \), it will also turn out to be true that \( s B (1 + \varepsilon_l) < 1 \). This in turn ensures that the worker’s optimal choice of \( \ln x \) is as follows.

\[
\ln x = \frac{1}{1 - s \beta (1 - \alpha) (1 + \varepsilon_l)} \left[ \ln n + \ln (s B) + (1 + \varepsilon_l) \ln (1 - \tau) + (1 - s) (1 + \varepsilon_l) \ln \mu_q \right. \\
+ \ln E \left[ \xi^{s (1+\varepsilon_l)} \right] + s (1 + \varepsilon_l) \ln A \]

Next, using the fact that \( \ln q = \alpha \ln n + \beta (1 - \alpha) \ln x \), and matching coefficients, \( B \) is:

\[ B = \frac{\alpha + \beta (1 - \alpha)}{1 + s \alpha (1 + \varepsilon_l)}. \]

This can in turn be used to solve for \( \ln A \) in terms of \( x \).

\[
\ln A = \alpha \ln n - \frac{\alpha - \beta (1 - \alpha) s \alpha (1 + \varepsilon_l)}{1 + s \alpha (1 + \varepsilon_l)} \ln x
\]

\( A \) can then be eliminated to yield a new expression for \( \ln x \).

\[
\ln x = \frac{1 + s \alpha (1 + \varepsilon_l)}{1 - s \beta (1 - \alpha) (1 + \varepsilon_l)} \ln n + \frac{1}{1 - s \beta (1 - \alpha) (1 + \varepsilon_l)} \left[ \ln s + \ln \left( \frac{\alpha + \beta (1 - \alpha)}{1 + s \alpha (1 + \varepsilon_l)} \right) \right. \\
+ (1 + \varepsilon_l) \ln (1 - \tau) + (1 - s) (1 + \varepsilon_l) \ln \mu_q + \ln E \left[ \xi^{s (1+\varepsilon_l)} \right] \right]
\]

Finally, since \( x \) inherits the log-normality of \( n \), and \( \ln q = \alpha \ln n + (1 - \alpha) \beta \ln x \), \( q \) is also log-normal. This means that the values of \( \mu_q \) and \( \sigma_q^2 \) can be found by matching coefficients.

\[
\sigma_q^2 = \left[ \frac{\alpha + \beta (1 - \alpha)}{1 - \beta s (1 - \alpha) (1 + \varepsilon_l)} \right]^2 \sigma_n^2
\]

\[
\ln \mu_q = \frac{1}{1 - (1 - \alpha) \beta (1 + \varepsilon_l)} \left[ \alpha + \beta (1 - \alpha) \right] \ln n + \frac{\beta (1 - \alpha)}{1 - (1 - \alpha) \beta (1 + \varepsilon_l)} \left[ \ln s + \ln \left( \frac{\alpha + \beta (1 - \alpha)}{1 + s \alpha (1 + \varepsilon_l)} \right) \right. \\
+ (1 + \varepsilon_l) \ln (1 - \tau) + \ln E \left[ \xi^{s (1+\varepsilon_l)} \right] \right]
\]

\[
\times \left\{ \ln s + \ln \left[ \frac{\alpha + \beta (1 - \alpha)}{1 + s \alpha (1 + \varepsilon_l)} \right] + (1 + \varepsilon_l) \ln (1 - \tau) + \ln E \left[ \xi^{s (1+\varepsilon_l)} \right] \right\}
\]
\[
+ \frac{\sigma_n^2}{2} \left[ \frac{\alpha + \beta (1 - \alpha)}{1 - s (1 - \alpha) \beta (1 + \varepsilon_l)} \right] \left[ \frac{\alpha + \beta (1 - \alpha)}{1 - (1 - \alpha) \beta (1 + \varepsilon_l)} \right]
\]

The elasticity of productivity follows directly.

\[
\frac{d \ln \mu_q}{d \ln (1 - \tau)} = \left( \frac{\beta (1 - \alpha) (1 + \varepsilon_l)}{1 - \beta (1 - \alpha) (1 + \varepsilon_l)} \right)
\]

Finally, the elasticity of income can be found as follows.

\[
\frac{d \ln z}{d \ln (1 - \tau)} = \frac{\partial z}{\partial (1 - \tau)} + \frac{\partial \ln (1 - \tau)}{\partial \ln q} \frac{d \ln q}{d \ln (1 - \tau)} + \frac{\partial \ln z}{\partial \ln \mu_q} \frac{d \ln \mu_q}{d \ln (1 - \tau)}
\]

\[
= \varepsilon_l + (1 + \varepsilon_l) \left[ \frac{\beta (1 - \alpha) (1 + \varepsilon_l)}{1 - \beta (1 - \alpha) (1 + \varepsilon_l)} \right] + \frac{\beta (1 - \alpha) (1 + \varepsilon_l)}{1 - \beta (1 - \alpha) (1 + \varepsilon_l)} (1 - s)
\]

\[
= \varepsilon_l + (1 + \varepsilon_l) \beta (1 - \alpha)
\]

\[
\frac{1}{1 - \beta (1 - \alpha) (1 + \varepsilon_l)}
\]

Proof of Proposition 11. Using the results from Proposition 10, a worker’s expected utility, \(\overline{v}_n\), can be derived in the same way as in Proposition 2.

\[
\overline{v}_n = n \frac{s(1+\varepsilon_l)[\alpha+\beta(1-\alpha)]}{1-\beta s(1-\alpha)(1+\varepsilon_l)} \left[ (1-\tau)(1+\varepsilon_l) \mu_q^{(1-s)(1+\varepsilon_l)} E \left( \varepsilon^{s(1+\varepsilon_l)} \right) \right] \frac{1}{1-\beta s(1-\alpha)(1+\varepsilon_l)} [sB]^{1-\beta s(1-\alpha)(1+\varepsilon_l)}
\]

\[
\times \left[ 1 - \frac{(1 + \varepsilon_l) sB}{1 + \varepsilon_l} \right] + \tau \overline{z}
\]

where \(B = \frac{\alpha + \beta (1 - \alpha)}{1 + \alpha (1 + \varepsilon_l)}\). The expected after-tax income for an individual with investment cost \(n\) can be derived similarly.

\[
(1-\tau) \overline{z}_n = n \frac{s(1+\varepsilon_l)[\alpha+\beta(1-\alpha)]}{1-\beta s(1-\alpha)(1+\varepsilon_l)} \left[ (1-\tau)(1+\varepsilon_l) \mu_q^{(1-s)} E \left( \varepsilon^{s(1+\varepsilon_l)} \right) \right] \frac{1}{1-\beta s(1-\alpha)(1+\varepsilon_l)} [sB]^{1-\beta s(1-\alpha)(1+\varepsilon_l)}
\]

\[
\times E \left[ \varepsilon^{s(1+\varepsilon_l)} \right] ^{1-\beta s(1-\alpha)(1+\varepsilon_l)} [sB]^{1-\beta s(1-\alpha)(1+\varepsilon_l)}
\]

The welfare of workers with ability \(n\) can then be re-written in terms of income, and weighted by \(\psi_n\).

\[
\psi_n \overline{v}_n = (1 - \tau) \psi_n \overline{z}_n \left[ 1 - \frac{(1 + \varepsilon_l) sB}{1 + \varepsilon_l} \right] + \tau \psi_n \overline{z}
\]

Differentiating \(\psi_n \overline{v}_n\) with respect to \(1 - \tau\), we obtain the effects on welfare of both the mechanical transfer and the distortion from the unproductive component of investment,
which is built into $\tau_n$. Then taking the expectation over ability types, $n$, we obtain:

$$\text{MEU} = E [\tau_n \psi_n] \left[ \frac{1}{1 + s \alpha (1 + \varepsilon_l)} \right] - \psi \bar{z}$$

Next, we can calculate the belief externality. This is again captured by the effect via $\mu_q$. Using the elasticities from Proposition 10 and the expression for $\tau_n$, the effect on the welfare of a worker with ability $n$ is:

$$\frac{(1 + \varepsilon_l) (1 - s)}{1 - \beta s (1 - \alpha) (1 + \varepsilon_l)} \frac{\tau_n - \tau \bar{z}}{\mu_q} \frac{\beta (1 - \alpha) (1 + \varepsilon_l)}{1 - \beta (1 - \alpha) (1 + \varepsilon_l)} \frac{\mu_q}{1 - \tau}.$$

Weighting by $\psi_n$, using the expression for $\tau_n$ and taking the expectation over ability types, this gives us the total belief externality.

$$\text{BE} = (1 - s) E [\tau_n \psi_n] \left[ \frac{1}{1 + s \alpha (1 + \varepsilon_l)} \right] \frac{\beta (1 - \alpha) (1 + \varepsilon_l)}{1 - \beta (1 - \alpha) (1 + \varepsilon_l)}$$

Finally, the fiscal externality follows from the elasticity of income.

$$\text{FE} = \tau \left[ \frac{\varepsilon_l + (1 + \varepsilon_l) \beta (1 - \alpha)}{1 - \beta (1 - \alpha) (1 + \varepsilon_l)} \right] \frac{\bar{z}}{1 - \tau}$$

By the same argument as Proposition 2, the sum of $\text{BE}$, $\text{MEU}$ and $\text{FE}$ must be zero for $\tau$ to be optimal, which yields the result.

$$\frac{\tau}{1 - \tau} = 1 - E_n \left( \frac{\tau_n \psi_n}{\psi} \right) \left[ \frac{1}{1 + s \alpha (1 + \varepsilon_l)} \right] \left[ 1 + (1 - s) \left( \frac{(1 + \varepsilon_l) \beta (1 - \alpha)}{1 - \beta (1 - \alpha) (1 + \varepsilon_l)} \right) \right]$$

Proof of Lemma 3. Firm beliefs about the distribution of productivity in the population must be confirmed in equilibrium and identical across firms. Let $\pi$ denote the equilibrium set of beliefs. Firm $j$’s expectation of the worker’s productivity is $E [q|\theta, \pi, A_j = 1] \geq 0$. Finally, let $\tilde{u}(C_j) = u(z_j - T(z_j), l_j)$ represent the utility that the worker receives from accepting offer $C_j$.

Suppose that some firm $j$ makes strictly positive expected profits given its contract offer $C_j$. It must then be the case that $\tilde{u}(C_j) \geq \tilde{u}(C_k)$ for all contracts $C_k$ offered by other firms. There are several cases to consider, each of which will lead to a contradiction.

Case 1: $\tilde{u}(C_j) > \tilde{u}(C_k)$ for some $C_k$. 

89
Firm $k$ initially earns zero expected profit, since not workers accept its offer. However, it can replicate $C_j$ but slightly reduce $l_j$. By doing so, it attracts the worker with probability one and earns strictly positive profits. This is a profitable deviation.

**Case 2:** $\tilde{u}(C_j) = \tilde{u}(C_k)$ for all $C_k$, and $\overline{P}_{k,\theta} \leq 0$ for some $k$.

If any firm makes weakly negative profits, then the same deviation as Case 1 applies.

**Case 3:** $\tilde{u}(C_j) = \tilde{u}(C_k)$ and $P_{k,\theta} > 0$ for all $k$.

Since the worker always accepts an offer, $E[q|\theta, \pi, C_j]$ is bounded weakly below $E[q|\theta, \pi]$ for at least one firm. This firm’s expected profit is bounded below $\overline{P}_{\text{MAX}}$.

$$\overline{P}_{\text{MAX}} = \max_{l, z} E[q|\theta, \pi] l - z \quad \text{s.t.} \quad u(z - T(z), l) \geq u(T(0), 0)$$

The assumptions on the worker’s utility function ensure that this yields finite labor supply for any finite $E[q|\theta, \pi]$. Since $z_j$ is restricted to be greater than zero and $E[q|\theta, \pi]$ is finite, $\overline{P}_{\text{MAX}}$ is also bounded. Finally, this firm can strictly increase its profit by reducing $l_j$ slightly and attracting the worker with probability one.

Since every case in which a firm makes a strictly positive expected profit implies a profitable deviation, and all firms can obtain at least zero expected profit by offering a contract with $z_j = 0$, it must be true that every firm makes zero expected profit.

Next consider two cases for the worker’s effective wage and labor supply.

**Case A:** One firm hires the worker with probability one.

If one firm $j$ always hires the worker in equilibrium, zero profit implies directly that the worker’s wage is her expected marginal product.

$$w_j = \frac{z_j}{l_j} = E[q|\theta, \pi]$$

Next, suppose that $C_j$ specifies a labor supply $l_j \notin L^*$ where:

$$L^* = \arg\max_{l_j} u\left(E[q|\theta, \pi] l_j - T\left(E[q|\theta, \pi] l_j\right), l_j\right).$$

Some other firm $k$ could offer a contract with the same implied wage as $C_j$ but with $l_k \in L^*$. Since $w_j = E[q|\theta, \pi]$, this produces zero profits but the worker’s utility is strictly higher. Firm $k$ can now increase $l_k$ slightly, thereby attracting the worker with probability one and earning strictly positive profit. Thus, it must be that $l_j \in L^*$.  

90
Case B: Multiple firms hire the worker with positive probability.

Since each firm earns zero profit, a similar wage condition must hold for firms who hire a worker with positive probability.

\[ w_j = \frac{z_j}{T_j} = E[q|\theta, \pi, A_j = 1] \forall j \]

Moreover, similar logic to above implies that \( l_j \in L_j^* \) where:

\[ L_j^* = \arg \max_{l_j} u(E[q|\theta, \pi, A_j = 1] \tilde{\ell}_j - T(E[q|\theta, \pi, A_j = 1] \tilde{\ell}_j), \tilde{\ell}_j) \]

Otherwise, firm \( j \) could offer a contract with the same implied wage but with \( l_j \in L_j^* \), so that \( \tilde{u}(C_j) \) is higher than before. It could then slightly increase \( l_j \). The worker would always accept the firm’s offer and it earns strictly positive expected profit.

Next, suppose \( E[q|\theta, \pi, A_j = 1] > E[q|\theta, \pi, A_k = 1] \) for some firms \( j \) and \( k \). For at least one pair, it must be that \( E[q|\theta, \pi, A_j = 1] > E[q|\theta, \pi] > E[q|\theta, \pi, A_k = 1] \). Let \( l_j^* \in L_j^* \) be the labor supply offered by firm \( j \). By the definition of \( L_j^* \) we know that:

\[ u(w_jl_j^* - T(w_jl_j^*), l_j^*) \geq u(w_kl_k^* - T(w_kl_k^*), l_k^*) \]

Suppose now that \( u(w_jl_j^* - T(w_jl_j^*), l_j^*) \leq u(w_kl_k^* - T(w_kl_k^*), l_k^*) \). Then firm \( j \) can alter its offer to \( z_j = w_kl_k^* < w_jl_j^* \) and set \( l_j \) below but arbitrarily close to \( k \). Firm \( j \) then attracts the worker with probability one. Since \( E[q|\theta, \pi] > E[q|\theta, \pi, A_k = 1] \), firm \( j \) can make strictly positive profit with this strategy.

Alternatively, suppose that \( u(w_jl_j^* - T(w_jl_j^*), l_j^*) > u(w_kl_k^* - T(w_kl_k^*), l_k^*) \), which implies that \( u(w_jl_j^* - T(w_jl_j^*), l_j^*) > u(w_kl_k^* - T(w_kl_k^*), l_k^*) \). This is a contradiction since we assumed that both firms attract the worker with positive probability. which requires that \( u(w_jl_j^* - T(w_jl_j^*), l_j^*) = u(w_kl_k^* - T(w_kl_k^*), l_k^*) \).

In conclusion, firms must earn zero expected profit, and \( E[q|\theta, \pi, A_j = 1] = E[q|\theta, \pi] \). □

Proof of Proposition 4. Assume – subject to verification – that formal education and unobservable investment are jointly log-normally distributed.

\[
\begin{bmatrix}
\ln x \\
\ln e
\end{bmatrix} \sim \mathcal{N}\left(\begin{bmatrix}
\ln \mu_x - (1 - \rho_i)^2 \frac{\sigma_x^2}{2}
\ln \mu_e - (1 - \rho_i)^2 \frac{\sigma_e^2}{2}
\end{bmatrix}, \begin{bmatrix}
\sigma_x^2 & \rho_i \sigma_x \sigma_e \\
\rho_i \sigma_x \sigma_e & \sigma_e^2
\end{bmatrix}\right)
\]

91
where: $\sigma_x^2$ and $\sigma_e^2$ are the equilibrium variances of $x$ and $e$, and $\rho_i$ is the correlation between the two investments.

This implies the following conditional distribution of $x$.

$$\ln x \sim \mathcal{N} \left( \ln \mu_x - (1 - \rho_i) \frac{\sigma_x^2}{2} + \rho_i \frac{\sigma_x}{\sigma_e} \left( \ln e - \ln \mu_e + (1 - \rho_i) \frac{\sigma_e^2}{2} \right), (1 - \rho_i)^2 \sigma_x^2 \right)$$

Given this, employers face a log-normal signal extraction problem. Conditional on observable investment level $e$ and signal $\theta$, the expectation of log-investment is as follows.

$$E (\ln x | \theta, e) = \bar{s} \ln x + (1 - \bar{s}) \left[ \ln \mu_x + \rho_i \frac{\sigma_x}{\sigma_e} \left( \ln e - \ln \mu_e + (1 - \rho_i) \frac{\sigma_e^2}{2} \right) \right] - \frac{1}{2} \frac{(1 - \rho_i)^2 \sigma_x^2 + \sigma_e^2}{(1 - \rho_i)^2 \sigma_x^2 + \sigma_e^2} + \bar{s} \ln \xi$$

where $\bar{s} = \frac{(1 - \rho_i)^2 \sigma_x^2 + \sigma_e^2}{(1 - \rho_i)^2 \sigma_x^2 + \sigma_e^2}$ is the signal-to-noise ratio for $\theta$ conditional on $e$.

Next, we can calculate a worker’s wage, which is equal to her marginal product. Noting that $E (\ln q) = \beta \alpha \ln e + \beta (1 - \alpha) E (\ln x)$, we have:

$$\ln w = \kappa_e \ln e + \kappa_x \ln x + \ln \tilde{\mu}_x$$

where:

$$\kappa_e = \beta \alpha + \beta (1 - \alpha) (1 - \bar{s}) \rho_i \frac{\sigma_x}{\sigma_e}$$

$$\kappa_x = \beta (1 - \alpha) \bar{s}$$

$$\ln \tilde{\mu}_x = \beta (1 - \alpha) (1 - \bar{s}) \left[ \ln \mu_x - \rho_i \frac{\sigma_x}{\sigma_e} \left( \ln \mu_e - (1 - \rho_i) \frac{\sigma_e^2}{2} \right) \right]$$

Exponentiating, the level of after-tax wages is: $w = (1 - \tau) e^{\kappa_e x \kappa_x} \tilde{\mu}_x \xi_{\kappa_e}$ and labor supply is $l = (1 - \tau)^{\varepsilon_l} w^{\varepsilon_l}$. After-tax income is therefore $(1 - \tau) z = \left[ (1 - \tau) e^{\kappa_e x \kappa_x} \tilde{\mu}_x \xi_{\kappa_e} \right]^{1 + \varepsilon_l}$.

Finally, expected utility is:

$$(1 - \tau)^{1 + \varepsilon_l} \tilde{\mu}_x^{(1 + \varepsilon_l)} E \left[ \xi_{\kappa_e(1 + \varepsilon_l)} \frac{e^{\kappa_e(1 + \varepsilon_l)x \kappa_x(1 + \varepsilon_l)}}{1 + \varepsilon_l} - k_x - k_e (1 - \tau_e) e + \tau z - \tau e \bar{K} \xi_{\kappa_e} \right].$$

Assuming that $\kappa_x (1 + \varepsilon_l) < 1$ and $\kappa_e (1 + \varepsilon_l) < 1$ so that individual decisions are
characterized by their first-order conditions, the optimal choices are as follows.

\[ x = \left( \frac{\kappa_x (1 - \tau)^{1 + \varepsilon_l} \xi_x^{1 + \varepsilon_l} e^{\kappa_x (1 + \varepsilon_l)} E \left[ \xi^{\kappa_x (1 + \varepsilon_l)} \right]}{k_x} \right)^{1 - \kappa_x (1 + \varepsilon_l)} \]

\[ e = \left( \frac{\kappa_e (1 - \tau)^{1 + \varepsilon_l} \xi_x^{1 + \varepsilon_l} e^{\kappa_x (1 + \varepsilon_l)} E \left[ \xi^{\kappa_x (1 + \varepsilon_l)} \right]}{k_e (1 - \tau_e)} \right)^{1 - \kappa_e (1 + \varepsilon_l)} \]

Solving this pair of simultaneous equations yields explicit solutions.

\[
\ln x = \frac{(1 + \varepsilon_l) \ln (1 - \tau) + \ln \bar{\xi}_x [1 - \kappa_x (1 + \varepsilon_l)] \ln \kappa_x + \kappa_e (1 + \varepsilon_l) \ln \kappa_e + E \left[ \xi^{\kappa_x (1 + \varepsilon_l)} \right]}{1 - (\kappa_x + \kappa_e) (1 + \varepsilon_l)} \\
- \frac{[1 - \kappa_x (1 + \varepsilon_l)] \ln k_x + [1 - \kappa_e (1 + \varepsilon_l)] \ln k_e - \kappa_x (1 + \varepsilon_l) \ln (1 - \tau_e)}{1 - (\kappa_x + \kappa_e) (1 + \varepsilon_l)} \\
\ln e = \frac{(1 + \varepsilon_l) \ln (1 - \tau) + \ln \bar{\xi}_x + \kappa_x (1 + \varepsilon_l) \ln \kappa_x + [1 - \kappa_x (1 + \varepsilon_l)] \ln \kappa_e + E \left[ \xi^{\kappa_x (1 + \varepsilon_l)} \right]}{1 - (\kappa_x + \kappa_e) (1 + \varepsilon_l)} \\
- \frac{\kappa_x (1 + \varepsilon_l) \ln k_x + [1 - \kappa_x (1 + \varepsilon_l)] \ln k_e - \kappa_x (1 + \varepsilon_l) \ln (1 - \tau_e)}{1 - (\kappa_x + \kappa_e) (1 + \varepsilon_l)} \tag{68} \tag{69}
\]

These two equations can be written in matrix form:

\[
\begin{bmatrix}
\ln x \\
\ln e
\end{bmatrix} = c + B 
\begin{bmatrix}
\ln k_x \\
\ln k_e
\end{bmatrix}
\]

where \( c \) is a 2 \times 1 vector of constants, and \( B \) is a 2 \times 2 matrix of constants. Since \( k_x \) and \( k_e \) are jointly log-normal, so are \( x \) and \( e \). This proves the first part of the proposition.

Using the equations for \( \ln x \) and \( \ln e \) above, it is straightforward to derive the elasticities of \( x \) and \( e \) with respect to \( 1 - \tau \) and \( 1 - \tau_e \).

\[
\varepsilon_{x\tau} = \frac{1 + \varepsilon_l}{1 - (\kappa_x + \kappa_e) (1 + \varepsilon_l)} \\
\varepsilon_{x\tau_e} = -\frac{\kappa_e (1 + \varepsilon_l)}{1 - (\kappa_x + \kappa_e) (1 + \varepsilon_l)} \\
\varepsilon_{e\tau} = \frac{1 + \varepsilon_l}{1 - (\kappa_x + \kappa_e) (1 + \varepsilon_l)} \\
\varepsilon_{e\tau_e} = -\frac{1 - \kappa_x (1 + \varepsilon_l)}{1 - (\kappa_x + \kappa_e) (1 + \varepsilon_l)}
\]

Using the fact that \( \ln q = \beta \alpha \ln e + \beta (1 - \alpha) \ln x \), we can then derive the elasticities of overall productivity with respect to \( 1 - \tau \) and \( 1 - \tau_e \).

\[
\varepsilon_{q\tau} = \frac{\beta (1 + \varepsilon)}{1 - (\kappa_x + \kappa_e) (1 + \varepsilon_l)} \\
\varepsilon_{q\tau_e} = -\frac{\beta \alpha [1 - \kappa_x (1 + \varepsilon_l)] + \beta (1 - \alpha) \kappa_e (1 + \varepsilon_l)}{1 - (\kappa_x + \kappa_e) (1 + \varepsilon_l)}
\]

93
In turn, the elasticities of income with respect to $1 - \tau$ and $1 - \tau_e$ are as follows.

$$
\varepsilon_{z\tau} = \varepsilon_l + (1 + \varepsilon_l) \frac{\beta (1 + \varepsilon)}{1 - (\kappa_x + \kappa_e)(1 + \varepsilon_l)}
$$

$$
\varepsilon_{z\tau_e} = -(1 + \varepsilon_l) \beta \alpha [1 - \kappa_x (1 + \varepsilon_l)] + \beta (1 - \alpha) \kappa_e (1 + \varepsilon_l)
$$

With the elasticities in hand, we can derive a first-order condition for the optimal tax and education subsidy. There are again three first-order effects of a change in the income tax. First, there is the fiscal externality, which takes into account the effect of re-optimization on both government revenue and expenditure on the education subsidy.

$$
\text{FE} (\tau) = \tau \frac{\overline{\psi \varepsilon_{z\tau} \tau}}{1 - \tau} - \tau_e \frac{dk_e e}{d(1 - \tau)}
$$

Second, there is the belief externality, which is similar to before.

$$
\text{BE} (\tau) = E_i \left[ \psi_i \frac{\partial v_i}{\partial \mu_x} \frac{\partial \mu_x}{\partial \varepsilon_{z\tau} \tau} \frac{\mu_x}{1 - \tau} \right]
$$

$$
= \beta (1 - \alpha) (1 - \bar{s}) E \left[ \psi_{k_e, k_x z_k_e, k_x} \right] \varepsilon_x
$$

Finally, there is the mechanical effect of the transfer.

$$
\text{ME} (\tau) = E \left[ \psi_{k_e, k_x} \varepsilon_{k_e, k_x} \right] - \overline{\psi \varepsilon}
$$

The three effects of a change in the education subsidy, $\tau_e$, are similar. First, there is the fiscal externality.

$$
\text{FE} (\tau_e) = \frac{\tau}{1 - \tau_e} \frac{\overline{\psi \varepsilon_{z\tau_e} \tau_e}}{1 - \tau_e} - \frac{\tau_e}{1 - \tau_e} \frac{\overline{\psi \varepsilon_{e\tau_e} k_e e}}{k_e e}
$$

Then there is the belief externality.

$$
\text{BE} (\tau_e) = \beta (1 - \alpha) (1 - \bar{s}) E \left[ \psi_{k_e, k_x z_k_e, k_x} \right] \varepsilon_{x\tau_e}
$$

Finally, there is the mechanical effect.

$$
\text{ME} (\tau_e) = \overline{\psi k_e e} - E \left[ \psi_{k_e, k_x} k_e e_{k_e, k_x} \right]
$$

Setting the sum of the three effects equal to zero for each instrument, and using the result that $k_e e_{k_e, k_x} = \kappa_e \left( \frac{1 - \tau}{1 - \tau_e} \right) \overline{z_{k_e, k_x}}$, the first-order conditions for the optimal tax and
education subsidy are as follows.

\[
\frac{\tau}{1-\tau} = \kappa_e \left( \frac{\tau_e}{1-\tau_e} \right) \left( \frac{\varepsilon_{e\tau}}{\varepsilon_{z\tau}} \right) + \frac{1-\gamma}{\varepsilon_{z\tau}} \gamma \left( 1-s \right) \varepsilon_{q\tau} \tag{70}
\]

\[
\frac{\tau_e}{1-\tau_e} = \frac{1}{\kappa_e} \left( \frac{\tau}{1-\tau} \right) \left( \frac{\varepsilon_{z\tau_e}}{\varepsilon_{e\tau_e}} \right) + \frac{1-\gamma}{\varepsilon_{e\tau_e}} \gamma \left( 1-s \right) \varepsilon_{q\tau} \tag{71}
\]

where:

\[
s = \frac{\beta \alpha \varepsilon_{e\tau} + \beta (1-\alpha) \tilde{s}x_{\tau}}{\beta \alpha \varepsilon_{e\tau} + \beta (1-\alpha) \varepsilon_{x\tau}} = 1 - \beta (1-\alpha) \left( 1-\tilde{s} \right) \frac{\varepsilon_{x\tau}}{\varepsilon_{q\tau}}.
\]

The statistic \(s\) is the fraction of the social return to higher productivity that workers fails to capture due to employers’ imperfect information about \(x\), when they re-optimize in response to changes in \(\tau\).

Solving the simultaneous equations above yields the first-order conditions for the optimal tax and education subsidy shown in the proposition.

\[
\frac{\tau}{1-\tau} = M_\tau \left[ \frac{1-\gamma}{\varepsilon_{z\tau}} - \frac{\gamma \left( 1-s \right) \varepsilon_{q\tau}}{\varepsilon_{z\tau}} \right] \tag{72}
\]

\[
\frac{\tau_e}{1-\tau_e} = M_{\tau_e} \left[ \frac{1-\gamma}{\varepsilon_{z\tau}} - \frac{\gamma \left( 1-s \right) \varepsilon_{q\tau}}{\varepsilon_{z\tau}} \right] \tag{73}
\]

The constants are the following functions of the elasticities.

\[
M_\tau = \frac{\kappa_e \left( \frac{\varepsilon_{e\tau}}{\varepsilon_{e\tau_e}} \right) + 1}{1 - \left( \frac{\varepsilon_{z\tau_e}}{\varepsilon_{e\tau_e}} \right) \left( \frac{\varepsilon_{e\tau}}{\varepsilon_{z\tau}} \right)}
\]

\[
M_{\tau_e} = \frac{1}{\kappa_e} \left( \frac{\varepsilon_{e\tau_e}}{\varepsilon_{e\tau_e}} \right) + \frac{\varepsilon_{z\tau}}{\varepsilon_{e\tau_e}}
\]

\[
\text{Proof of Proposition 5.} \quad \text{See Stantcheva (2014).}
\]

\[
\text{Proof of Proposition 6.} \quad \text{I begin by establishing that there is an equilibrium with zero investment. The stated assumptions ensure that} \quad w(\theta|\pi) \quad \text{is strictly increasing in} \quad \pi, \quad \text{that} \quad w(\theta|0) = 0 \quad \text{for all} \quad \theta \quad \text{and that} \quad w(\theta|1) = \omega \quad \text{for all} \quad \theta. \quad \text{This guarantees that} \quad \overline{w}_q(0|\tau) = \overline{w}_u(0|\tau) \quad \text{and} \quad \overline{w}_q(1|\tau) = \overline{w}_u(1|\tau), \quad \text{which in turn implies that} \quad G(\beta(0|\tau)) = 0 \quad \text{and} \quad G(\beta(1|\tau)) = 0. \quad \text{Thus, there is a solution with no investment and no solution in which all agents invest.}
\]

\[
\text{Finally, if} \quad G(\beta(\hat{\pi}|\tau)) > \pi \quad \text{for some} \quad \pi^* \quad \text{then the continuity of} \quad \phi(\theta) \quad \text{and} \quad G \quad \text{combined with the fact that} \quad G(\beta(1|\tau)) = 0 \quad \text{implies that} \quad G(\beta(\hat{\pi}|\tau)) = \hat{\pi} \quad \text{for some} \quad \hat{\pi} > \pi^*. \quad \text{There are therefore at least two solutions to equilibrium condition 46.}
\]
Proof of Proposition 7. Social welfare is given by:

\[ \pi \overline{v}_q (\pi) + (1 - \pi) \overline{v}_u (\pi) - \int_0^{\tau(\pi) - \tau_u(\pi)} kdG (k). \]

where:

\[ \overline{v}_q (\pi|\tau) = \int_0^1 v (\theta|\pi) dF_q (\theta) - k \]
\[ \overline{v}_u (\pi|\tau) = \int_0^1 v (\theta|\pi) dF_u (\theta). \]

By differentiating the equation for the worker’s wage, it can be shown that the wage is increasing in \( \pi \).

\[ \frac{\partial w (\theta|\pi)}{\partial \pi} = \omega \times \frac{f_u (\theta) f_q (\theta)}{[\pi f_q (\theta) + (1 - \pi) f_u (\theta)]^2} > 0 \]

In turn, this means that \( v (\theta|\pi, \tau) = v ((1 - \tau) w (\theta|\pi) + \tau \pi w) \) is increasing in \( \pi \). Thus, holding investment decisions and \( \tau \) constant, welfare increases with \( \pi \). The accompanying change in individual investment decisions can only make those marginal individuals better off. Thus, welfare is higher for all workers.

Next, let \( \pi^* (\tau) \) be the investment rate in the planner’s preferred equilibrium for each tax rate. The proof that \( \pi^* (\tau) \) rises as \( \tau \) falls is simple. First, if \( \pi^* (\tau) = 0 \), it cannot fall. Alternatively, suppose that \( \pi^* (\tau_0) > 0 \). Since lowering \( \tau \) from \( \tau_0 \) to \( \tau_1 \) raises \( G (\beta (\pi|\tau)) \) for any \( \pi \), it must be true that \( G (\beta (\pi^* (\tau_0) | \tau_1)) > \pi^* (\tau_0) \). Since \( G (\beta (\pi|\tau)) \) is continuous and \( G (\beta (1|\tau)) = 0 \), there must be some higher investment rate \( \hat{\pi} \) such that \( G (\beta (\hat{\pi} | \tau_1)) = \hat{\pi} > \pi^* (\tau_0) \). Since the equilibrium with the highest investment rate Pareto dominates all others, the planner’s preferred equilibrium now features a higher investment rate. \[\Box\]

Proof of Proposition 8. Just as in Sections 3 and 4, there are three effects from a fall in \( \tau \). First, there is a mechanical effect. For a worker with signal \( \theta \), this is as follows.

\[ \frac{\partial v (\theta|\pi)}{\partial (1 - \tau)} = u' \left[ (1 - \tau) \omega \frac{\pi f_q (\theta)}{f_q (\theta) + (1 - \pi) f_u (\theta)} + \tau \pi \omega \frac{\pi f_q (\theta) - \pi f_u (\theta)}{f_q (\theta) + (1 - \pi) f_u (\theta)} \right] \]
\[ = u' \pi (1 - \pi) \omega \left[ \frac{f_q (\theta) - f_u (\theta)}{f_q (\theta) + (1 - \pi) f_u (\theta)} \right] \]

Aggregating up, we obtain the total mechanical effect on social welfare.

\[ \text{ME} = \omega \pi (1 - \pi) \int_0^1 u' [f_q (\theta) - f_u (\theta)] d\theta = -\omega \pi \overline{v}_r \]
Next, there is a fiscal externality. Assuming $\pi^\dagger(\tau)$ is locally continuous, this is given by:

$$\text{FE} = \tau \frac{d\pi}{d(1-\tau)} \omega \int_0^1 u'_\theta \left[\pi f_q(\theta) + (1-\pi) f_u(\theta)\right] d\theta = \frac{\tau}{1-\tau} \pi \varepsilon \omega \pi'_{\theta}$$

Finally, there is the externality via employer beliefs, which raises wages for all workers but is not taken into account when workers optimize. Using the continuity of $\pi^\dagger(\tau)$ again:

$$\text{BE} = (1-\tau) \frac{d\pi}{d(1-\tau)} \int_0^1 u'_\theta \left[\frac{\partial w(\theta|\pi)}{\partial \pi}\right] \left[\pi f_q(\theta) + (1-\pi) f_u(\theta)\right] d\theta$$

$$= \varepsilon \omega \int_0^1 u'_\theta \left[\frac{f_u(\theta) f_q(\theta)}{\pi f_q(\theta) + (1-\pi) f_u(\theta)}\right] d\theta = \varepsilon \pi \omega$$

Adding the three effects and re-arranging yields the following first-order condition.

$$\frac{\tau}{1-\tau} = \frac{(1-\pi) \int_0^1 u'_\theta \left[f_u(\theta) - f_q(\theta)\right] d\theta - \varepsilon \int_0^1 u'_\theta \left[\frac{f_u(\theta)f_q(\theta)}{\pi f_q(\theta) + (1-\pi)f_u(\theta)}\right] d\theta}{\varepsilon \int_0^1 u'_\theta \left[\pi f_q(\theta) + (1-\pi)f_u(\theta)\right] d\theta}$$

$$= \frac{v_\tau - \varepsilon \pi \omega}{\varepsilon}$$

Proof of Proposition 9. Fixing a value of $T_{A \rightarrow D}$, the proof that condition 48 must hold at the optimum is analogous to the proof of Proposition 8. A similar perturbation argument can be used to establish that condition 49 must hold. An increase in $T_{A \rightarrow D}$ leads to the following gain in welfare for type $A$ and $D$ individuals:

$$-\Delta_A = \frac{1}{\lambda_A} \int_0^1 u'_{A,\theta} dF(\theta) \quad \Delta_D = \frac{1}{\lambda_D} \int_0^1 u'_{D,\theta} dF(\theta)$$

The welfare gain, $\lambda_D \Delta_D - \lambda_A \Delta_A$, must be zero at interior optima if $\pi^\dagger(T)$ is locally continuous, implying condition 49.

H Empirical Evidence
(For Online Publication)

A. Calculating the Wedge Between Private and Social Returns

In this appendix, I show how to use an estimate of the speed of employer learning to calculate the implied wedge between private and social returns. To do so, I build on the empirical model developed by Lange (2007), which fits the empirical evidence patterns well. The procedure outlined here is how the statistics in Table 1 were calculated.
Following Lange (2007), I assume that the experience profile of log productivity is independent of other factors. An individual’s productivity can be written as:

\[ \ln q_{i,t} = \tilde{\chi}(e_i, m_i, \eta_i, a_i) + \tilde{H}(t_i) \]  

(74)

where: \( e_i \) is information available to both employers and the researcher (e.g., schooling); \( m_i \) is available to employers but not researchers (e.g., job interview performance); \( a_i \) is available to the researcher only (e.g., the skills measured by the AFQT); \( \eta_i \) captures factors that are initially hidden from both the researcher and employers; and \( t_i \) is experience.

Further assuming that \( \tilde{\chi} \) is linear (and suppressing the subscript for individual \( i \) from now on) allows us to write:

\[ \ln q_t = re + \alpha_1 m + \rho a + \eta + \tilde{H}(t) \]  

(75)

Then letting \((e, q, a, \eta)\) be jointly normally distributed, we can write \( a \) and \( \eta \) as:\(^{57}\)

\[ a = E[a | e, m] + v = \gamma_1 m + \gamma_2 e + v \]

\[ \eta = E[\eta | e, m] + u = \alpha_2 e + u \]

In turn, this allows us to express log productivity as a linear function of the information available to employers at experience level \( t = 0 \):

\[ \ln q = (r + \rho \gamma_2 + \alpha_2) e + (\alpha_1 + \rho \gamma_1) m + (\rho v + u) + \tilde{H}(t) \]

\[ = E(\tilde{\chi} | e, m) + (\rho v + u) + \tilde{H}(t) \]

Still following Lange (2007), the process of employer learning is modeled as follows. After each period, a noisy measure of \( \theta_t \) of \( \tilde{\chi} \) becomes available to all employers.

\[ \theta_t = \tilde{\chi} + \varepsilon_t \]  

(76)

The noise in this signal, \( \varepsilon_t \), is i.i.d. normal with variance \( \sigma^2_{\varepsilon} \). It is uncorrelated with all the other variables. Thus, after \( t \) years of experience, a \( t \)-dimensional vector of measurements \( \theta^t = (\theta_0, \theta_1, \ldots, \theta_{t-1}) \) has become available to employers.

Given this employer learning process, an employer’s rational belief about a worker’s productivity after after \( t \) years of experience is characterized by the posterior distribution:

\[ \mu_t = (1 - \lambda_t) E(\tilde{\chi} | e, m) + \lambda_t \left( \frac{1}{t} \sum_{i=0}^{t-1} \theta_i \right) \]

\[ \sigma^2_t = \frac{\sigma^2_0 \sigma^2_{\varepsilon}}{t \sigma^2_0 + \sigma^2_{\varepsilon}} \]  

(77)

\(^{57}\)As in Lange (2007), we can normalize the coefficient vector and suppress \( m \) from the equation for \( \eta \).
where $\sigma_0^2$ is the variance of $\tilde{\chi}$ conditional on $(e, m)$—i.e., the variance of the initial expectation error $(\lambda v + e)$.

In equation 77, the weight $\lambda_t$ is given by the following equation.

$$\lambda_t = \frac{tK}{1 + (t-1)K} \quad (78)$$

Here, $K_1 = \frac{\sigma_0^2}{(\sigma_0^2 + \sigma_e^2)}$ is the speed of employer learning, which measures the information content of initial information relative to subsequent measurements. From here, it is straightforward to show that a worker’s competitive wage is given by:

$$\ln W(e, m, \theta^t) = (1 - \lambda_t) E(\tilde{\chi} | s, m) + \lambda_t \left( \frac{1}{t} \sum_{t=0}^{t-1} y_t \right) + H(t) \quad (79)$$

where $H(t) = \bar{H}(t) + \frac{1}{2} \sigma_t^2$.

Lange (2007) shows how to use this result to estimate the speed of employer learning, $K$. However, our focus here is different. Given an estimate of $K$, I will examine the implications for the discounted return to an increase in a worker’s productivity.

An individual’s expected lifetime earnings until retirement in period $T$ is:

$$\sum_{t=0}^{T} \delta^t E[W(e, m, \theta^t) | s, m, z]$$

where $\delta$ is the discount rate. Combining this equation with the wage given by equation 79 we obtain the following expression for the present value of earnings:

$$\sum_{t=0}^{T} \delta^t E\left[ \exp\left( (1 - \lambda_t) E(\tilde{\chi} | s, m) + \lambda_t \left( \frac{1}{t} \sum_{t=0}^{t-1} \theta_t \right) + H(t) | s, m, z, \eta \right) \right]$$

Finally, we can ask what the return is to an increase in $\tilde{\chi}$ that is not initially rewarded by employers.\textsuperscript{58}. This private return is given by:

$$\sum_{t=0}^{T} \delta^t \lambda_t E[W(e, m, \theta^t) | s, m, z, \eta] \quad (80)$$

By contrast, the social return is simply given:

$$\sum_{t=0}^{T} \delta^t E[W(e, m, \theta^t) | s, m, z, \eta].$$

\textsuperscript{58}Specifically, this implies that $E(\tilde{\chi} | s, m)$ is unaffected. This calculation is supported by Lange’s (2007) results, which indicate that there is no initial return to higher ability as measured by the AFQT.
The share of the social return to higher $\chi$ that is captured by workers is simply given by the ratio of the two expressions.

$$s = \frac{\sum_{t=0}^{T} \delta^t \lambda_t E \left[ W \left( e, m, \theta^t \right) \mid s, m, z, \eta \right]}{\sum_{t=0}^{T} \delta^t E \left[ W \left( e, m, \theta^t \right) \mid s, m, z, \eta \right]}$$  \hspace{1cm} (81)

Equation 81 is equivalent to equation 19, but now shows that three empirical objects are required to estimate of the share of the return to investment, $s$, that is captured by workers. First, we need an estimate of the speed of employer learning, which implies $\lambda_t$. Table 1 provides four such estimates. Second, we need the lifecycle profile of expected wages, which I take from Lagakos et al. (2018). Finally, we need a discount rate.

Figure H1 shows how the pieces fit together. It displays the impact of higher unobservable productivity on wages at each level of potential experience, assuming that $K = 0.259$ and $\delta = 0.95$. The social impact is normalized to one at zero years of experience. It then rises as wages increase, but becomes discounted heavily in later periods. The private return starts at zero, but then converges to the social return in later years as a worker’s skill becomes evident. The ratio of the blue shaded area in panel (b) to the total shaded area is the fraction of the discounted social return that is not captured by workers.

Each estimate in Table 1 was calculated in this way for different values of the discount rate and the speed of employer learning. All of the estimates imply a meaningful distortion of the returns to investment. As Figure H1 shows, this is due to a relatively large gap between private and social returns over the first decade of a worker’s career.

**B. Heterogeneity in Employer Learning by Productivity Level**

In the next part of this appendix, I build on Arcidiacono et al. (2010) to provide more direct evidence on how learning varies over the productivity distribution. Taking AFQT as a proxy for productivity, I adapt equation 20 by interacting the variables of interest with indicators $I_A = \mathbb{1}(\text{AFQT} > m)$ and $I_B = \mathbb{1}(\text{AFQT} \leq m)$ for whether a worker’s AFQT score is above or below the median, $m$.

$$\ln w = \sum_{j \in \{A, B\}} \left\{ \rho_{0,j} \text{AFQT} + \rho_{1,j} \text{AFQT} \times \text{Experience} \right. $$

$$+ \gamma_{0,j} \text{Education} + \gamma_{1,j} \text{Education} \times \text{Experience} $$

$$+ \lambda_{0,j} + \lambda_{1,j} \text{Exper.} + \lambda_{2} \text{Exper.}^2 + \lambda_{3} \text{Exper.}^3 \} \times I_j + X' \beta + \varepsilon \hspace{1cm} (82)$$

The sample follows Arcidiacono et al. (2010),\(^{59}\) It restricts to black and white men who are employed, have wages between one and one hundred dollars, and at least eight years

\(^{59}\)Appendix Table II provides summary statistics for workers with high and low AFQT scores.
Figure H1: Private and Social Impact of Higher Productivity

Figure notes. This figure shows the impact of a higher level of initially unobservable productivity on wages at each level of potential experience. The initial social impact is normalized to one. The social impact then rises as wages increase, but becomes discounted heavily in later periods. The private return to higher productivity is initially zero, but converges to the social return in later years as the worker’s skill becomes evident. Panel (a) shows the undiscounted impacts, while panel (b) shows the discounted impacts. The ratio of the blue shaded area to the total shaded area in panel (b) is the fraction of the discounted social return that is not captured by workers. The speed of learning is set to 0.259 as estimated by Lange (2007), and the lifecycle wage profile is taken from Lagakos et al (2018).
of education. Following Altonji and Pierret (2001), I also limit the analysis to workers with fewer than 13 years of experience – measured as the number of years a worker has spent outside of school. Employment in the military, at home, or without pay is excluded.

*Table notes.* Dependent variable is the worker’s log hourly wage multiplied by 100. AFQT is a worker’s score on the armed forces qualification test, standardized by age to have zero mean and unit standard deviation. Education and experience are measured in years. Standard errors, shown in parentheses, are clustered at the worker level. All regressions include an indicator for urban vs. rural, race, race × experience, and region and year fixed effects. Data are from the National Longitudinal Survey of Youth (NLSY79). The sample is restricted to working black and white men who have wages between one and one hundred dollars, at least eight years of schooling and fewer than 13 years of experience. NLSY sample weights are used.

Table 1 shows the results. The dependent variable is the log of each worker’s real hourly wage, multiplied by 100; and AFQT scores are standardized to have mean zero and unit standard deviation for each age at which the test was taken. The coefficient on AFQT is therefore approximately the percentage wage gain associated with a one standard

---

60 The relationship between log wages, AFQT and experience is approximately linear in this region.
deviation higher AFQT score. The coefficient on the interaction of AFQT with experience is the number of percentage points that this gain increases by with each year of experience.

Below the median, there is strong evidence of learning. The weight on AFQT rises steeply with experience, and the weight on education falls. There is less evidence of learning above the median, where the coefficient on the interaction between AFQT and experience is close to zero. The large direct effect of AFQT in the upper half of the distribution suggests that the results are not driven by AFQT scores being unimportant at the high end; and the less negative interaction between education and experience above the median suggests that differences in learning are driving the results.

I Simulation of the Model

(For Online Publication)

This appendix provides detailed information on the methods I use to simulate the full model. The first step is to discretize the signal space into \( n_\theta \) possible values, and categorize individuals into \( n_q \) groups, each with a different productivity decision. I then use the noise and productivity distributions to define an \( n_q \times n_\theta \) matrix \( B_0 \), which maps productivity decisions to distributions of realized signals.

A. Evaluation of a Single Perturbation

Evaluation of a perturbation proceeds as follows. First, define a perturbation that raises the tax rate on income between \( z \) and \( \overline{z} \) by \( \Delta T' \). This yields a new tax schedule, \( T_1 \).

\[
T'_1(z) = \begin{cases}
T_0'(z) + \Delta T' & \text{if } z \in [\underline{z}, \overline{z}) \\
T_0'(z) & \text{otherwise}
\end{cases}
\]

Take the existing wage given each \( \theta \) but apply \( T_1 \) instead of \( T_0 \). Re-optimize labor supply decisions and calculate \( v(w(\theta|\pi_0)|T_1) \) for each \( \theta \), yielding a candidate vector of utilities \( v_1^{(0)} \). Using \( v_1^{(0)} \), calculate \( E_\theta(v(\theta|\pi_0,T_1)|q) \) and adjust workers’ investment decisions toward their preferred choice. This yields a new distribution of productivity, \( \delta_1^{(0)}(q|\pi_0,T_1) \).

In the discretized space, \( \delta_1^{(0)}(q|\pi_0,T_1) \) implies a new candidate vector of productivity choices \( q_1^{(1)} \). Use these choices to reconstruct a new candidate \( B_1^{(1)} \) matrix. Then solve for employers’ rational productivity inferences at each value of \( \theta \), yielding a candidate set of employer beliefs \( \pi_1^{(1)}(q) \) and a hypothesized vector of wages \( w_1^{(1)} \).

\[
w_1^{(1)} = \left[ \text{diag} \left( B_1^{(1)'} \times \delta_1^{(1)}(q|\pi_1^{(1)},T_1) \right) \right]^{-1} \times \left[ B_1^{(1)'} \times \text{diag} \left( q_1^{(1)} \right) \times \delta_1^{(1)}(q|\pi_1^{(1)},T_1) \right]
\]

Recalculate utilities to obtain \( v_1^{(1)} \) and adjust workers’ investment decisions again, yield-
ing \( q^{(2)} \). Iterate this process until individuals do not want to adjust their investment decisions given the hypothesized employer beliefs: i.e., when
\[
\pi_1^{(k)}(q) \approx \delta_1^{(k)} \left( q \mid \pi_1^{(k)}(q) , T_1 \right).
\]
At this point, the process has converged.

Once this inner fixed point has been obtained, compare the new value of expected utility for each level of costs, weight using the assumed social welfare function, and adopt the perturbation if and only if it produced an increase in average social welfare.

**B. Decomposition of a Perturbation**

The effect of a perturbation on equilibrium social welfare can be decomposed into its three components: the mechanical effect (\( \text{ME} \)), the fiscal externality (\( \text{FE} \)) and the belief externality (\( \text{BE} \)). To calculate the mechanical effect, hold all decisions (wages, labor supply and investment) constant and evaluate the mechanical change in welfare. The belief externality can be calculated by comparing the true gain in expected utility to the gain holding fixed the wage paid at each level of \( \theta \). Finally, the fiscal externality can be evaluated by subtracting the behavioral effect on tax revenue from all individuals’ incomes.

**C. Solving for the Optimal Tax Schedule**

To solve for the optimal tax schedule, simply consider a series of perturbations as defined above. Define a size for each perturbation, \( \Delta T \). Then divide the income distribution into \( n_b \) tax brackets. Loop through the tax brackets and calculate the gain in welfare from a perturbation in each direction. Adopt the perturbation that increases welfare, then move to the next bracket. Repeat until there are no perturbations that increase welfare. Optionally, reduce the size of each perturbation and repeat.

**D. Recovery of Fundamentals**

To back out fundamentals for the simulation described in Section 5, I begin with the Pareto log-normal approximation of the United States wage distribution provided by Mankiw et al. (2009). Next, I use this wage distribution, and the posited log-normal conditional signal distribution, to infer a productivity distribution that produces this wage schedule.

The specific procedure that I follow is to parameterize a Champernowne distribution for log wages with density proportional to:

\[
\frac{1}{2} \exp \left( \alpha (z - z_0) \right) + \lambda + \frac{1}{2} \exp \left( -\alpha (z - z_0) \right)
\]

To choose the parameters, I use MATLAB’s \( \text{fminunc} \) function to solve for the set of parameters that jointly minimize the Kullback-Leibler divergence between the target wage distribution \( f_w \) and the simulated distribution \( f_w^{\text{sim}} \).
\[ D_{KL} \left( f_w || f_w^{\text{sim}} \right) = \sum_w f_w (w) \ln \left( \frac{f_w (w)}{f_w^{\text{sim}} (w)} \right) \]

As Figure 8 shows, this process is effective.

For each wage, I can then calculate utility \( v (w (\theta | \pi) | T_0) \), given an initial tax system \( T_0 \), by solving workers’ labor supply problems for each value of \( \theta \). Expected utility for each level of productivity is then given by:

\[ E_\theta (v (\theta | \pi_0, T_0) | q) = B_0 \underbrace{\ldots}_{n_\theta \times 1} \times \underbrace{v_0}_{n_\theta \times 1} \]

where \( v_0 \) is a vector that stacks the utility realized at each value of \( \theta \) and \( \pi_0 \) denotes employers’ current and correct beliefs about the distribution of productivity. Combined with individuals’ productivity choices and a value of \( \beta \), this vector of expected utilities can then be used to back out an implied cost distribution.

**E. Optimal Tax Rates at Higher Income Levels**

The discussion in Section 5 focuses on the impact of the belief externality on optimal marginal tax rates between $0 and $300,000. At higher levels of income, the externality becomes less important for social welfare – and the tax adjustment lower – because it primarily affects individuals with low social welfare weight. Figure 12 shows the impact on the optimal tax schedule at higher levels of income, from $300,000 up to around $4 million. Because the extended exercise is very computationally intensive, the size of the tax brackets is larger for this extended exercise.

**F. Alternative Utility and Welfare Functions**

For the simulation introduced in Section 5, I assumed that workers have quasilinear utility, and that social welfare is the average of types’ log expected utilities.

\[ U = c - l^{1 + \frac{1}{\varepsilon_l}} / \left( 1 + \frac{1}{\varepsilon_l} \right) - kx \quad \mathcal{W} (T) = \int_K \ln (\mathbb{E}U_k) \, dG (k) \quad (83) \]

An alternative is to assume that agents are risk averse over realized consumption, and that the social welfare function is linear.

\[ U = \ln \left( c - l^{1 + \frac{1}{\varepsilon_l}} / \left( 1 + \frac{1}{\varepsilon_l} \right) \right) - kx \quad \mathcal{W} (T) = \int_K \mathbb{E}U_k dG (k) \quad (84) \]

Results with this specification are shown in Figure 13. The results are qualitatively similar to those from the simulation in Section 5. As before, marginal tax rates are generally lower.
**Figure I1: Optimal Tax Schedule from Alternative Starting Points**

![Graph showing optimal tax schedules from different starting points](image)

*Figure notes.* This figure shows the results of simulations as described in Section 5 but starting from different initial tax schedules. Each line shows the optimal tax schedule found using the iterative procedure described here. There remain very minor differences, which could be eliminated only at great computational expense.

**Figure I2: Optimal Tax Rates at Higher Income Levels**

![Graph showing optimal tax rates at higher income levels](image)

*Figure notes.* This figure shows the results of a simulation as described in Section 5 when it is extended to higher levels of income. The graph starts at $300,000 and extends to around $4 million. The solid red line shows the optimal tax schedule, while the dashed blue line shows a tax schedule that would be accepted by a naïve social planner who sets the sum of the mechanical effect and fiscal externality equal to zero. For computational reasons, the tax function is discretized into $100,000 brackets rather than $20,000 brackets.
**Figure I3: Utilitarian Non-linear Taxation with Risk Aversion**

![Graph showing optimal tax schedule and naive social planner's tax schedule](image)

*Figure notes:* This figure shows the results of a simulation as described in Section 5 except that agents are risk averse and the planner is utilitarian. The solid red line shows the optimal tax schedule, while the dashed blue line shows a tax schedule that would be accepted by a naïve social planner who sets the sum of the mechanical effect and fiscal externality equal to zero. The tax function is discretized into $20,000 brackets.

under the optimal than the naïve tax schedule, and the “U” shape of the tax schedule is amplified when the belief externality is taken into account.

There are, however, important quantitative differences. First, marginal tax rates are higher with risk aversion under both the optimal and naïve tax schedules. In part, this is because risk aversion lowers the elasticity of taxable income to around 0.6. In addition, the specification with risk aversion implies a larger benefit to redistribution; the reason for this is that marginal social welfare weights decline more steeply with income, because the planner seeks to equalize realized rather than expected utilities.

Second, the downward adjustment when the belief externality is taken into account is shifted toward lower incomes. In part, this is again because marginal social welfare weights decline more sharply with realized income; this implies that a given wage impact from the externality matters more at lower incomes than before, and less at higher incomes. In addition, the adjustment to marginal tax rates is slightly smaller because the ratio of the elasticity of productivity to the elasticity of taxable income is lower.

**G. Adding Non-Discretionary Expenditures**

The quantitative exercises throughout the paper focus on redistributive taxation. They therefore assume that there is no separate non-discretionary expenditure requirement.
Figure notes. This figure shows the results of a simulation as described in Section 5 except that the government is required to set aside $5,000 to cover non-discretionary expenditures that do not add to individual utilities. The solid red line shows the optimal tax schedule, while the dashed blue line shows a tax schedule that would be accepted by a naïve social planner who sets the sum of the mechanical effect and fiscal externality equal to zero. The tax function is discretized into $20,000 brackets.

Mathematically, the results are changed if the product of any such expenditure enter individual utilities directly: in this case, the income tax schedule simply needs to be thought of as including the entire system of taxes and expenditures. However, the analysis does change slightly if any such expenditures do not enter individual utilities.

Figure I4 shows the results with a $5,000 per person exogenous revenue requirement. They are largely unchanged except that marginal tax rates are slightly higher, especially at the low end. Most importantly, the downward adjustment between the naïve and optimal tax schedules is similar with and without the revenue requirement.

H. Incidence of the Belief Externality

As I highlighted in Sections 4 and 5, the incidence of the belief externality matters for its effect on welfare. This is because the affected individuals vary in their levels of labor supply, marginal tax rates, and welfare weights. Figure I5 provides a type of decomposition to shed further light on how incidence matters. First, in each tax bracket, I calculate the true impact of the belief externality by following the procedure outlined in part B, above. The solid red line in Figure I5 shows the results, scaled to be relative to the change in average productivity in response to that perturbation.
The remaining lines show what the impact of the belief externality on social welfare would be if we were to abstract from the factors that contribute to the incidence being important. First, the dotted gray line shows what the impact would be if all individuals supplied the average amount of labor, faced the average marginal tax rate, and had the same average welfare weight placed upon them. The dashed blue line takes into account each affected individual’s true level of labor supply to get variation in the pre-tax income impact of the externality. Next, the dashed orange line translates the pre-tax income impact into consumption by allowing marginal tax rates to vary. The remaining difference between the orange and solid red lines is due to variation in welfare weights.

As would be expected based on the equilibrium relationship between productivity and a worker’s expected wage, the wage impact of the externality rises initially and then slowly declines as incomes rise. When differences in labor supply are taken into account, the impact is skewed further toward higher incomes. Differences in marginal tax rates then accentuate the inverse-U shape of the incidence. Finally, declining marginal social welfare weights reduce the welfare impact at high incomes. On net, we are left with a strong inverse-U shaped pattern in the impact of the belief externality on welfare.

I. ADDITIONAL FIGURES AND TABLES

Table I1 provides summary statistics for data used to test for employer learning in Section 5. Figures I6 to I8 compare the mechanical effect, fiscal externality and belief externality between the naïve and optimal tax schedules, in each tax bracket for the simulation in Section 5. Figure I9 shows the expected net transfer from the government for workers of each initial productivity level. Figure I10 plots the utility gain for workers with at each initial productivity level. Finally, Figure I11 shows the change in marginal social welfare weights starting from naïve taxation and transitioning to optimal taxation.

---

61 At very low incomes, this adjustment amplifies a negative impact on high income individuals enough so that the average consumption impact is negative, although the final impact on social welfare is still positive.
Figure I5: Incidence of the Belief Externality

Figure notes. This figure provides a more detailed analysis of the importance of incidence for the impact of the belief externality. The solid red line shows the true impact of the belief externality that arises in response to a small marginal tax cut in each tax bracket, scaled to be relative to the change in average productivity in response to that perturbation. The dotted gray line shows what the impact would be if all individuals supplied the average amount of labor, faced the average marginal tax rate, and had the same average welfare weight placed upon them. The dashed blue line takes into account each affected individual’s true level of labor supply, and the dashed orange line allows the marginal tax rate to vary. The remaining difference between the orange and blue lines is due to variation in welfare weights.
