

Identification and characterization of the contact zone between short-tailed shrews (*Blarina*) in Iowa and Missouri

C.W. Thompson, R.S. Pfau, J.R. Choate, H.H. Genoways, and E.J. Finck

Abstract: Short-tailed shrews (genus *Blarina* Gray, 1838) are characterized by divergent karyotypes and are genetically distinct. *Blarina* species are similar morphologically but, in most cases, can be distinguished morphometrically. *Blarina* distributions tend to be parapatric along well-defined contact zones; however, it has been suggested that the northern short-tailed shrew (*Blarina brevicauda* (Say, 1823)) and Elliot's short-tailed shrew (*Blarina hylophaga* Elliot, 1899) occur sympatrically in Iowa and Missouri. To evaluate this possibility, 179 specimens were collected in southwestern Iowa and northwestern Missouri. Karyotypes and total length were used for field identification, and amplified fragment length polymorphism (AFLP) analysis was used to verify field identifications and to investigate the extent of hybridization. One hundred seventy-eight of 179 specimens were identified to species. The one exception had a karyotype of *B. brevicauda* ($2n = 50$, FN = 48); however, AFLP analysis indicated that this individual was likely an F₁ hybrid. No backcrosses were detected, so it appears that introgression is minimal. The putative hybrid was trapped at a locality with *B. brevicauda* just north of a locality having only *B. hylophaga*. No locality contained both species. Therefore, these species are not broadly sympatric as has been suggested, but rather exhibit a distribution similar to the pattern of parapatry seen in most of the contact zones of *Blarina*.

Résumé : Les musaraignes à queue courte (du genre *Blarina* Gray, 1838) se caractérisent par des caryotypes divergents et sont génétiquement distinctes. Les espèces de *Blarina* sont semblables morphologiquement, mais dans la plupart des cas, la morphométrie permet de les distinguer. Les répartitions des *Blarina* ont tendance à être parapatriques le long de zones de contact bien définies; on croit néanmoins que la grande musaraigne à queue courte (*Blarina brevicauda* (Say, 1823)) et la musaraigne à queue courte d'Elliot (*Blarina hylophaga* Elliot, 1899) se retrouvent en sympatrie en Iowa et au Missouri. Afin de vérifier cette possibilité, nous avons récolté 179 spécimens dans le sud-ouest de l'Iowa et le nord-ouest du Missouri. Les caryotypes et la longueur totale nous ont servi pour les identifications de terrain et une analyse du polymorphisme des longueurs des segments amplifiés (AFLP) a permis de confirmer les identifications de terrain et de déterminer l'importance de l'hybridation. Des 179 spécimens, 178 ont été identifiés à l'espèce. La seule exception avait un caryotype de *B. brevicauda* ($2n = 50$, FN = 48); cependant l'analyse de ALFP indique que cet individu est vraisemblablement un hybride de F₁. Comme il n'y a aucune indication de rétrocroisement, l'introgression semble minimale. L'hybride putatif a été piégé dans une localité contenant *B. brevicauda* située juste au nord d'une localité où vit seulement *B. hylophaga*. Aucune localité ne contient les deux espèces. Les deux espèces ne possèdent donc pas une importante zone de sympatrie, comme on le croyait; ils ont plutôt une répartition parapatric du type observé dans la plupart des zones de contact de *Blarina*.

Introduction

Distributions of mammalian species in North America experienced several contractions and expansions during the Pleistocene owing to cyclical glacial activity and climatic changes. The Pleistocene glaciations certainly had an impact on current distributions of mammals on the Great Plains (Hoffmann and Jones 1970; Klicka and Zink 1997; Sepkoski

1998; Hewitt 2000; Lister 2004; Barnosky 2005). Speciation in the genus *Blarina* Gray, 1838 has been associated with Pleistocene glacial events (Graham and Semken 1976; Schmidly and Brown 1979; Jones et al. 1984). An interpretation of the fossil record suggests that *Blarina* diverged during the Irvingtonian North American Land Mammal Age (0.5–1.8 million years ago), perhaps owing to glacial events, which led to the isolation of a northern population that be-

†Deceased.

came the northern short-tailed shrew (*Blarina brevicauda* (Say, 1823)) and a southern population that later diverged during the Rancholabrean North American Land Mammal Age (10 000 – 500 000 years ago; Schmidly and Brown 1979; Jones et al. 1984). The southern speciation event resulted in Elliot's short-tailed shrew (*Blarina hylophaga* Elliot, 1899) in the west and the southern short-tailed shrew (*Blarina carolinensis* (Bachman, 1837)) in the east (Jones et al. 1984). A fourth species within the genus, Sherman's short-tailed shrew (*Blarina shermani* Hamilton, 1955), occurs in peninsular Florida but has not been linked to Pleistocene events (Benedict et al. 2006).

Three of these species have distinct karyotypes (*B. brevicauda*, *B. carolinensis*, and *B. hylophaga*; Genoways et al. 1977; George et al. 1981, 1982) and also can be distinguished easily with mitochondrial DNA (mtDNA) sequence data (Benedict 1999a, 1999b; Brant and Ortí 2002; Brant 2005; Reilly et al. 2005). Despite their genetic differences, *Blarina* species are similar morphologically but, in most instances, can be distinguished morphometrically (Blair 1939; Graham and Semken 1976; Jones et al. 1984; Kays and Wilson 2002; Reilly et al. 2005; Benedict et al. 2006). Wherever the distributions of these species approach, they exhibit parapatric relationships with little overlap at contact zones and little or no hybridization (Genoways and Choate 1972; Graham and Semken 1976; Bowles 1977; Ellis et al. 1978; Tate et al. 1980; Braun and Kennedy 1983; Jones et al. 1984; Benedict 1999b; Brant and Ortí 2002).

The best-studied contact zone between species of *Blarina* is between *B. brevicauda* and *B. hylophaga* (Fig. 1). Using morphometric characters, Jones (1964) first identified this contact zone in Nebraska. Genoways and Choate (1972) studied this contact zone further using morphometrics and discovered that it was narrow and parapatric with possible hybridization occurring. Using morphometrics and mtDNA sequence data, Benedict (1999a, 1999b) re-examined the contact zone in Nebraska and ascertained that it was 2.9 km wide at its widest point, again indicating a parapatric distribution (see Fig. 1). Benedict (1999a, 1999b) also concluded that occasional hybridization occurred but with little to no introgression.

Bowles (1975, 1977), also using morphometrics, confirmed the presence of the *brevicauda*–*hylophaga* contact zone in southwestern Iowa but found no indication of introgression. However, Moncrief et al. (1982) conducted a more detailed morphometric analysis of the contact zone in southern Iowa and northern Missouri and concluded that the two species occurred sympatrically in this area because of numerous intermediate-sized specimens (see Fig. 1). These findings are contrary to expectations given that the distribution is unquestionably parapatric in Nebraska and hybridization appears to be limited (Genoways and Choate 1972; Benedict 1999a, 1999b).

Given the conflicting results of these studies, a reassessment of the contact zone between these species in Iowa and Missouri is warranted. If these species are indeed sympatric in Iowa and Missouri but parapatric in Nebraska, there would be important implications regarding our understanding of contact zones with known hybridization (i.e., hybrid zones). There are few reported instances of broad sympatry occurring at contact zones between closely related species with low

mobility (Moore 1977). Because of the numerous contact zones between *Blarina* species in the eastern US, these species provide an ideal opportunity to test current models of hybridization. Before such studies can be conducted, however, the relationships between the species must be clarified.

Our study addresses two questions: (1) are *B. brevicauda* and *B. hylophaga* parapatric or sympatric in Iowa and Missouri and (2) what is the extent of hybridization and introgression where the geographic ranges of the two species abut or overlap? We hypothesize that *B. brevicauda* and *B. hylophaga* are parapatric in Iowa and Missouri, as they are in Nebraska (Genoways and Choate 1972; Benedict 1999a, 1999b). We further hypothesize based on the findings of Moncrief et al. (1982) that the two species hybridize and introgress more in Iowa and Missouri than in Nebraska, which would explain the presence of the intermediate-sized specimens. To address these questions, we collected specimens along multiple transects (using field-generated karyotypes and total length to locate the contact zone) and then used amplified fragment length polymorphism (AFLP) analysis (Vos et al. 1995) to confirm field identifications, identify potential hybrids, and determine the extent of introgression. If our first hypothesis is correct, and the two species are actually parapatric, we will find a clear absence of sympatry among specimens positively identified using karyotypes and AFLPs. If the two species introgress more in Iowa–Missouri than Nebraska, the width of the hybrid zone as determined from AFLPs will exceed the 2.9 km described by Benedict (1999a, 1999b).

Materials and methods

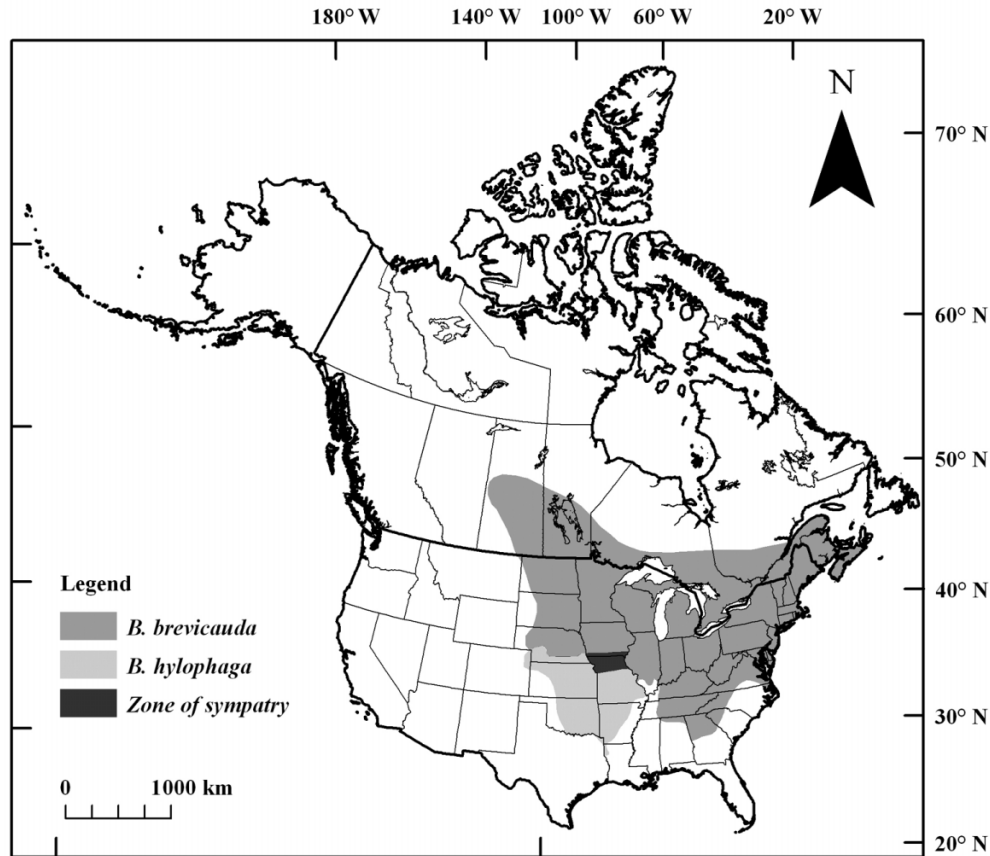

Study area

The study area included counties north of Interstate 70 in Missouri and south of Interstate 80 in Iowa and focused on those counties west of Interstate 35 in southwestern Iowa and northwestern Missouri. The counties sampled in Iowa included Fremont, Mills, Montgomery, Page, Pottawattamie, and Taylor. In Missouri, the counties included Andrew, Atchison, Buchanan, Caldwell, Clinton, Daviess, Gentry, Harrison, Holt, Nodaway, Platte, Ray, and Worth (Fig. 2).

Specimen collection

Trapping began in May 2005 in the Missouri River Valley at the location of the contact zone found by Benedict (1999b). The specific location was just west of Interstate 29 along Plum Creek in Fremont County, Iowa. Transects were placed in a north–south direction to locate populations of *B. brevicauda* to the north and *B. hylophaga* to the south (see Fig. 2). Trapping sites of 50 Sherman live-traps (H.B. Sherman Traps, Inc., Tallahassee, Florida, USA) were placed in road ditches to take advantage of potentially high densities of the genus *Blarina* (Kaufman and Kaufman 1989; Kirsch 1997). Traps were baited with dry oats and spaced approximately 10 m apart with two traps per station. GPS coordinates at the beginning and the end of each transect were recorded using a Garmin eTrex Legend (Garmin International, Inc., Olathe, Kansas, USA) GPS unit. After locating *B. brevicauda* in the north and *B. hylophaga* in the south, trapping shifted eastward approximately 50 km at the same latitude to begin a new transect. Specimens were identified

Fig. 1. Currently known geographic distributions of the northern short-tailed shrew (*Blarina brevicauda*) and Elliot's short-tailed shrew (*Blarina hylophaga*) in North America (George et al. 1982; Moncrief et al. 1982; Reilly et al. 2005). The distributions of both species, as well as the sympatric overlap of the distributions within Iowa and Missouri, are indicated in the map legend.

in the field by use of karyotypes and total length (described below). Trapping continued until November 2005 and traced the contact zone into Missouri to Interstate 35.

Collecting efforts resumed in May 2006. *Blarina* species were trapped as far as approximately 50 km north and south of the contact zone, with collecting efforts continuing beyond 50 km in the event that a contiguous line of the same species was not found. Additional specimens were collected within the probable contact zone to further refine its location and to analyze hybridization. The trapping protocol was the same as in 2005.

Reference specimens were collected in the summer and fall of 2006. These specimens were collected in Harrison County, Iowa (*B. brevicauda*), and Ellis County, Kansas (*B. hylophaga*), outside the study area and away from areas of known contact between the two species. Animal care and use methods followed the guidelines of the American Society of Mammalogists (Gannon et al. 2007). Voucher specimens are housed in the Sternberg Museum of Natural History, Fort Hays State University (MHP).

Field identification

Karyotypes were essential for positive field identification of species (Genoways et al. 1977; George et al. 1982; Thompson and Hoffman 2009). Only those individuals that were alive within a half hour prior to karyotyping or were still warm to the touch were karyotyped. Karyotyping was

performed as described by Baker et al. (2003) and are detailed by Thompson (2008).

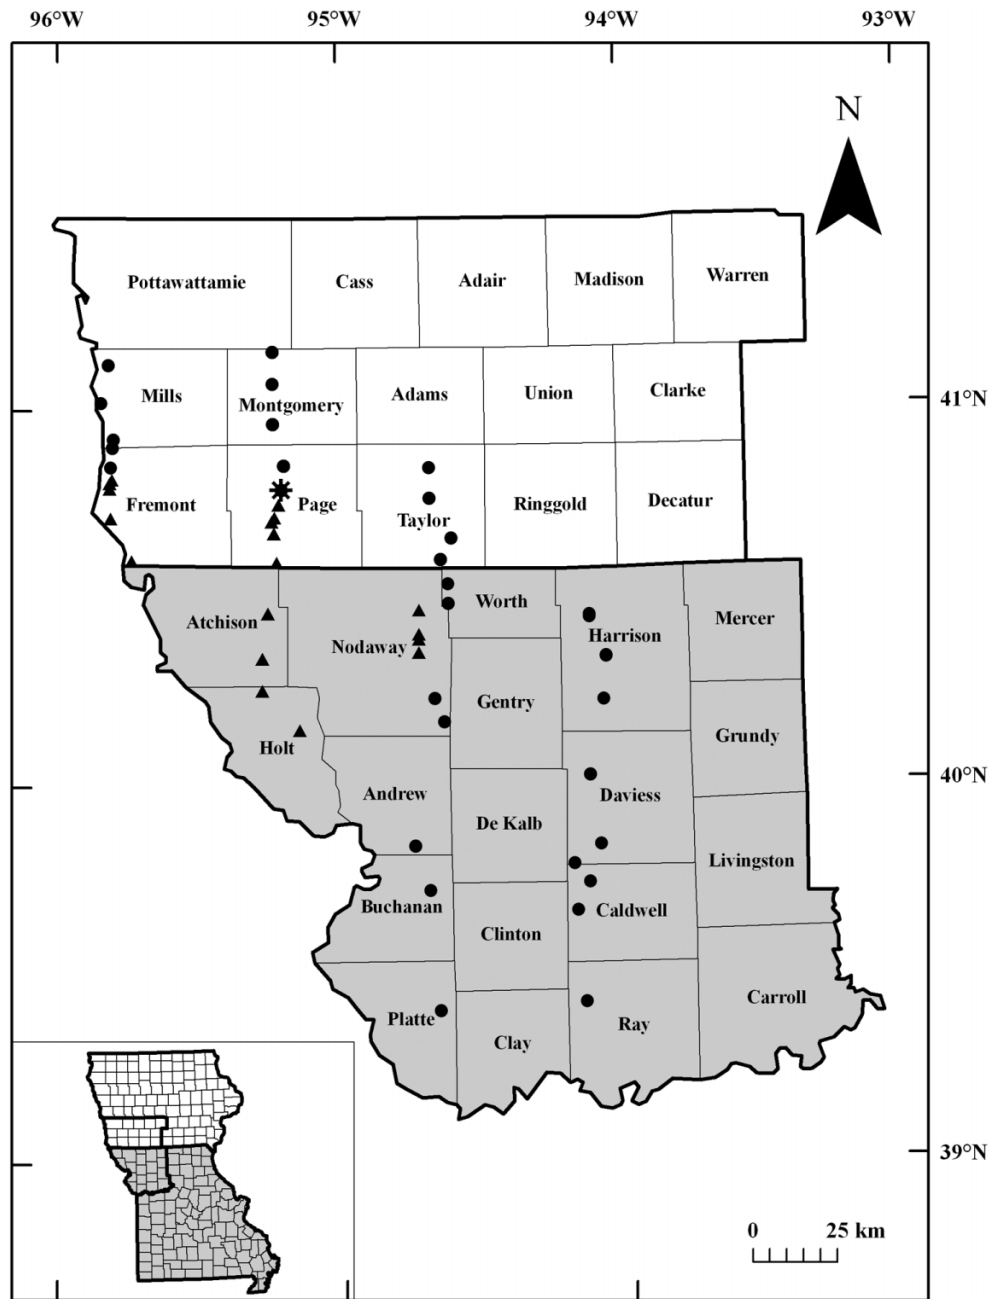

Metaphase chromosome spreads were located with a Nikon Alphaphot YS microscope (Nikon Corp., Tokyo, Japan). Diploid and fundamental numbers of chromosomes were counted for each spread. Five to 10 spreads were photographed for each slide with a Nikon Coolpix 950 digital camera (Nikon Corp.), except when fewer than five spreads were found or in the event that chromosomal counts were not consistent (Sullivan et al. 1986; Baker et al. 1989), in which the most frequent count was used.

All standard external measurements (total length, tail length, hindfoot length, ear length, and mass; Martin et al. 2001) were recorded to assess their usefulness in identification in the field. Total length was used to provide tentative identification of specimens not karyotyped in the field. Specimens for which total length was ≥ 120 mm were identified as *B. brevicauda*. Specimens for which total length was ≤ 110 mm were identified as *B. hylophaga*. Specimens with total length between 110 and 120 mm were considered to be ambiguous or possible hybrids (Bowles 1975; Benedict 1999a; Schwartz and Schwartz 2001).

AFLP analysis

AFLPs were used to provide additional information for identification of species, to document hybridization, and to determine the extent of introgression. The AFLP protocol

Fig. 2. Location of specimens collected in the study area in southwestern Iowa and northwestern Missouri. Solid circles indicate localities where northern short-tailed shrew (*Blarina brevicauda*) were collected. Solid triangles indicate localities where Elliot's short-tailed shrew (*Blarina hylophaga*) were collected. The asterisk indicates the location where the putative hybrid (MHP 37853) was trapped together with 10 specimens of *B. brevicauda*. Transects one to four are west to east in a north–south linear fashion. The inset shows the study area location (outlined) within Iowa (unshaded) and Missouri (shaded).

followed a technique (Phillips et al. 2007) modified from Vos et al. (1995). The following primer combinations were used: *EcoRI*-CAC and *AseI*-TAG, *EcoRI*-CAC and *AseI*-TCT, *EcoRI*-CAC and *AseI*-TGA, and *EcoRI*-CAT and *AseI*-TGA. Selective *EcoRI* primers were labeled fluorescently for detection by a Beckman–Coulter CEQ8000 Automated DNA Analysis System (Beckman–Coulter, Inc., Fullerton, California, USA). Beckman–Coulter software was used to size fragments based on an internal size standard. Only fragments that could be scored unambiguously as present or absent were in-

cluded in the data set, which consisted of a table of ones indicating the presence of fragments of a certain size and zeros indicating their absence. Patterns of genetic divergence among individuals were determined by using principal coordinate analysis (PCoA) in GenAlEx version 6.1 (Peakall and Smouse 2006). STRUCTURE version 2.2 (Falush et al. 2007) was used to estimate each individual's admixture proportion (*q*). The data file was formatted to take advantage of the ability of this version of STRUCTURE to account appropriately for the nature of dominant markers. Length of the

burn-in period and number of iterations was set at 10 000 and 50 000, respectively. The number of populations (K) was set to two, representing the two species, but prior information regarding identification of species was not considered. Five independent runs were performed and the admixture proportions were averaged. NewHybrids version 1.1 beta (Anderson and Thompson 2002) was used to infer hybrid-class membership by calculating the posterior probability of an individual falling into one of six hybrid classes (pure *B. hylophaga*, *B. hylophaga* backcross, F_1 , F_2 , *B. brevicauda* backcross, or pure *B. brevicauda*). Number of sweeps for burn-in and after burn-in was set to 10 000 and 50 000, respectively. Information regarding identification of species was not considered a priori. Defaults were selected for all other settings. Likelihood values from five independent runs were averaged.

Relationship in study area

Trapping locations were placed into ArcMap (ESRI (Environmental Systems Research Institute, Inc.), Redlands, California, USA) to assess the spatial relationship between the distributions of the two species of *Blarina*. The definition of parapatry followed that of Mallet (2005: 230), where “2 groups of populations or species are parapatric if they abut at their range boundaries”. This definition allows for gene flow between the groups but only at the limit of each species’ geographic range, which can lead to a narrow band of hybridization or hybrid zone (Mallet 2005). Thereby, the distributional relationship was determined to be parapatric if the ranges of the species abutted but did not overlap (Futuyma and Mayer 1980; Key 1981; Moulton et al. 1983; Bull 1991; Mallet 2005). The distributional relationship was determined to be sympatric if the ranges significantly overlapped.

Results

Specimen collection

In total, 203 specimens were collected. Twenty-four specimens were collected as reference samples from four sites outside the study area: 10 *B. brevicauda* were collected in Harrison County, Iowa, and 14 *B. hylophaga* were collected in Ellis County, Kansas. One hundred seventy-nine specimens were collected from 68 trapping locations along the four transects within the focal study area. Of those 179 specimens, 116 were collected in Iowa and 63 were collected in Missouri (see Appendix A). No individuals were collected in Pottawattamie County, Iowa, or Clinton and Gentry counties, Missouri.

Field identification

Eleven of the reference specimens were field karyotyped. Six specimens of *B. brevicauda* had a diploid number ($2n$) of 50 and one had 49 (all had a fundamental number (FN) of 48). Four specimens of *B. hylophaga* had a $2n$ of 52 (all had an FN of 60). Fifty-four of the 100 specimens examined karyotypically within the study area were identified as *B. brevicauda* and 46 as *B. hylophaga*. Diploid numbers for *B. brevicauda* within the study area were 50, 49, and 48 at a ratio of 27:19:7, respectively. Forty-four of these specimens had an FN of 48; the remaining nine specimens were not discernable. Diploid number for *B. hylophaga* within the study area was 52, and FN were 62, 61, or 60 at a ratio of 6:1:23, respectively.

Based on total length, 9 of the 24 reference specimens fell within the range expected of *B. brevicauda* and 14 within that expected of *B. hylophaga*. One specimen from within the range of *B. hylophaga* was intermediate. Also, 76 of the 179 specimens within the study area were designated as *B. brevicauda* and 67 as *B. hylophaga* (36 were intermediate).

AFLP analysis

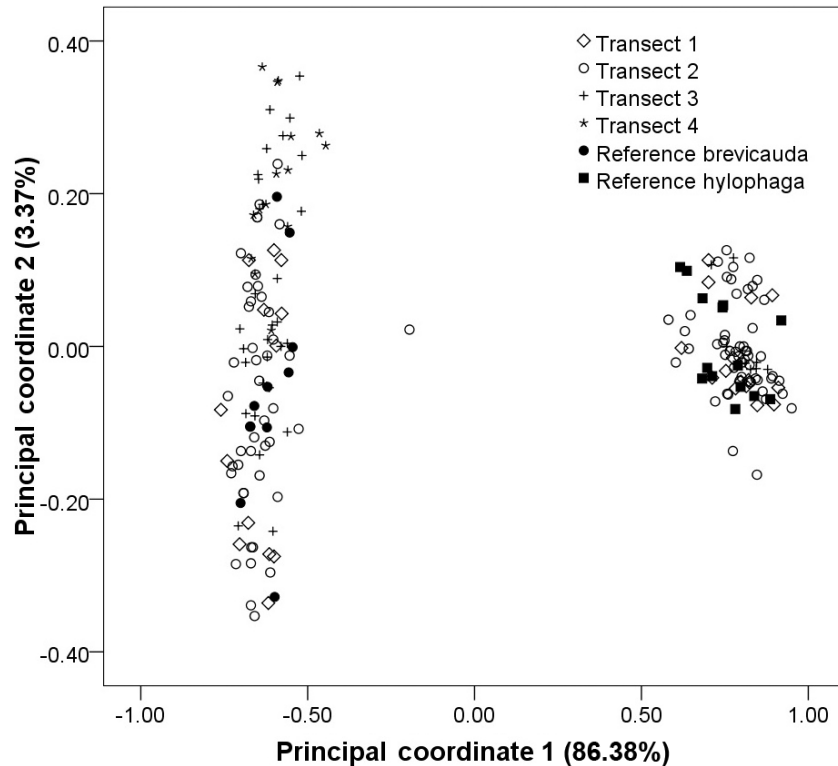

AFLP data were obtained for all 203 specimens. Ninety-two AFLP fragments were scored, with 59 (64.13%) being polymorphic. The first two axes of the PCoA explained 89.75% of the variation in the AFLP data, with axis one differentiating the two species (Fig. 3). All reference specimens were placed into one of two distinct clusters as expected, allowing for unambiguous genetic identification. All individuals from the study area except one (MHP 37853, from transect two) fell within one of the two clusters. STRUCTURE analysis gave mean admixture proportions (q) ranging from 96.2% to 99.9% for all individuals except MHP 37853, which had a mean admixture proportion of 67.2%. NewHybrids analysis identified one individual (MHP 37853) with a high mean likelihood of being an F_1 hybrid (83.7%); all other individuals had pure mean likelihood values ranging from 99.8% to 100%.

Identification using combined data

Using karyotypes and (or) AFLP data, all 24 specimens from the reference localities were assigned unambiguously to the correct species. Twenty-three of these specimens were assigned correctly based on total length. The single morphological intermediate was genetically verified as *B. brevicauda*. The 10 *B. brevicauda* averaged a total length of 122.8 ± 2.7 mm (mean \pm SD) (118–128 mm), tail length of 27.2 ± 1.5 mm (26–31 mm), hindfoot length of 14.0 ± 0.5 mm (13–15 mm), ear length of 0.0 ± 0.0 mm (no range), and mass of 19.5 ± 1.2 g (17–21.5 g). The 14 *B. hylophaga* averaged a total length of 105.7 ± 3.3 mm (100–110 mm), tail length of 24.4 ± 1.5 mm (12–28 mm), hindfoot length of 11.9 ± 0.5 mm (11–13 mm), ear length of 0.0 ± 0.0 mm (no range), and mass of 12.1 ± 1.2 g (10.5–15.0 g).

The 179 specimens from within the study area were identified unambiguously to species using karyotypes and (or) AFLP data. The 139 specimens assigned to species based on total length (excluding intermediates) were all assigned correctly. The individual identified as an F_1 hybrid (MHP 37853) using AFLP data was intermediate in size and had a *B. brevicauda* karyotype ($2n = 50$; FN = 48). *Blarina brevicauda* averaged a total length of 124.5 ± 7.5 mm (104–142 mm), tail length of 28.0 ± 2.7 mm (21–33 mm), hindfoot length of 14.1 ± 1.2 mm (8–19 mm), ear length of 0.0 ± 0.0 mm (no range), and mass of 18.9 ± 3.5 g (9.0–29.5 g). *Blarina hylophaga* averaged a total length of 106.3 ± 5.0 mm (95–118 mm), tail length of 22.0 ± 4.7 mm (8–29 mm), hindfoot length of 12.2 ± 0.7 mm (11–14 mm), ear length of 0.0 ± 0.0 mm (no range), and mass of 13.2 ± 2.2 g (8.5–18.5 g). The F_1 hybrid (MHP 37853) was a female and had a total length, tail length, hindfoot length, ear length, and mass of 119 mm, 28 mm, 14 mm, 0 mm, and 15.5 g, respectively.

Fig. 3. Plot of first two principal coordinates of the PCoA based on AFLP data of all specimens analyzed. Proportion of variation explained by each axis is indicated in parentheses. Specimens identified as the northern short-tailed shrew (*Blarina brevicauda*) are clustered on the left. Specimens identified as Elliot's short-tailed shrew (*Blarina hylophaga*) are clustered on the right. The putative hybrid (MHP 37853) is located intermediate to these two clusters.

Relationship in study area

The contact zone is not broadly sympatric, but rather it appears to be parapatric (Fig. 2). This contact zone is apparent in transects one and two in Fremont and Page counties, Iowa, respectively. The third transect shows *B. brevicauda* occurring both north and south of locations with *B. hylophaga* in Nodaway County, Missouri. All individuals to the south of Nodaway County were identified as *B. brevicauda*; therefore, transect three crossed the contact zone in two places, which indicated an eastward extension of the distribution of *B. hylophaga*. Additionally, transect four only yielded *B. brevicauda*. Therefore, the distribution of *B. hylophaga* within the study area appeared to be at its easternmost extent in either eastern Nodaway County or western Gentry and (or) Worth counties (Fig. 2).

The hybrid specimen (MHP 37853) was obtained together with 10 *B. brevicauda* at a locality of transect two in Page County, Iowa. Adjacent localities to the north and south had only specimens of *B. brevicauda* and *B. hylophaga*, respectively. The nearest pure parental localities within this transect were ~12.20 km apart. The nearest pure parental localities of transect one were separated by ~3.71 km. Distances between pure parental localities in transect three were ~8.89 and ~14.33 km in the north and south, respectively (Fig. 2).

Discussion

Characterization of the contact zone

The distributions of *B. brevicauda* and *B. hylophaga* in the study are not broadly sympatric (Fig. 2) as suggested by

Moncrief et al. (1982). Rather, our results support the hypothesis of parapatry. In fact, the location of the contact zone in our study (Fig. 2) closely matches the parapatric distributions documented by Bowles (1975, 1977), which suggests that the contact zone has moved minimally in the past 30 years. Benedict (1999a, 1999b) reported similar results with little movement of the contact zone in Nebraska since Genoways and Choate's (1972) study. The sympatric relationship observed by Moncrief et al. (1982) might have been the result of the inclusion of specimens from northeastern Kansas in the study specimens for *B. hylophaga*. It now is known that some of the specimens examined are from a presumed isolated population of *B. brevicauda* within this region of Kansas (Benedict 1999b). Given our finding of *B. brevicauda* in far western Missouri, it is possible that this population might not be isolated as once thought but rather might exist as an extension of *B. brevicauda* from Missouri into Kansas.

Benedict (1999b) noted that physical barriers separated the distributions between these two species in Nebraska. In this study, we found no obvious barrier along transects two and three. However, transect one is bisected by Plum Creek in Fremont County, Iowa, which separates the ranges of *B. brevicauda* and *B. hylophaga*. The strength of Plum Creek as a barrier seems low, given annual freezes during the winter months in this area and year-around activity of *Blarina* species (George et al. 1986; Genoways and Choate 1998). Roads also have been shown to be a barrier to the dispersal of *Blarina* species (Kirsch 1997; Benedict 1999b). Because of the large distances (3.71–14.33 km) separating the closest local-

ities of *B. brevicauda* and *B. hylophaga*, we were unable to verify if roads act as barriers within our study area.

Given the absence of obvious barriers, interspecific interactions might influence the geographic relationship between these two species at their contact zones. These interactions hypothetically are balanced by climatic factors (Mayr 1963; Smith 1965; Genoways and Choate 1972; Graham and Semken 1976; Tate et al. 1980; Bull 1991; Frey 1992; Shaw et al. 1993; Benedict 1999a, 1999b; Hewitt 2001; Holt and Keitt 2005). One of the climatic factors that has been suggested to have an impact on the distribution of *Blarina* is temperature (Neal and Lustick 1973; McNab 1979; Genoud 1988), which would account for distributional shifts during the Pleistocene and Holocene with the advancing and retreating continental glacier. The larger-bodied *B. brevicauda* would be better adapted to colder climate and would have advanced southward as the glacier advanced. The alternative movement would have occurred with small-bodied *B. hylophaga* shifting northward during hypsithermal periods. The current distribution is the result of competing thermal needs of the species and the current temperature regiment enforced by the karyotypic differences of the species. This hypothesis seems plausible because ecotonal changes, which are maintained by the climate, appear to be a strong limiting factor in species distributions at contact zones (Smith 1965; Moulton et al. 1983; Bull 1991; Frey 1992; Harrison 1993; Searle 1993; Shaw et al. 1993; Hewitt 2000, 2001). However, we know of no environmental barriers associated with the contact zone of *Blarina* in our study area, as was reported in Nebraska (Benedict 1999b). In such instances, interspecific interactions, such as competition, parasite transmission, and reproductive interference (Benedict 1999b), might be sufficient and necessary to maintain the observed parapatric relationship in light of no discernible transition in the environment (Smith 1965; Endler 1977; Bull 1991; Turelli et al. 2001).

Extent of hybridization and introgression

Only 1 individual was identified as a hybrid (F_1) of the 29 individuals (~3.45%) from the locality at which it was captured and the two adjacent localities combined. Benedict (1999a) reported a higher proportion of hybrids in Nebraska than is reported herein contrary to our original hypothesis. Given that Benedict (1999a, 1999b) collected many more individuals from the immediate vicinity of the contact zone, it is not surprising that he observed a greater proportion of hybrids. Additionally, Benedict's (1999a) technique of using morphology to identify hybrids would misclassify small *B. brevicauda* or large *B. hylophaga* as hybrids. Because we unambiguously identified specimens with karyotypes and AFLPs, we were able to assess the reliability of using morphology to identify hybrids. The potential for misclassification owing to the presence of small *B. brevicauda* and (or) large *B. hylophaga* near the contact zone is evident when looking at the extent of overlap in the ranges of external measurements seen among our genetically identified specimens. We observed a much greater range of measurements (thus greater overlap) at the study site relative to the reference sites. If we had relied only on the measurements from the reference site specimens to identify study site specimens, we would have a misidentification rate of 4.47% (8 of 179

specimens would be assigned to the incorrect species) based on total length (our most discriminating measurement based on reference site specimens). One of these eight specimens is the one identified as a hybrid based on AFLP analysis, which was within the size range of *B. brevicauda*. An additional 13.97% (25 of 179) were intermediate in size and might be presumed to be hybrids in the absence of karyotype or AFLP data.

We did not document introgression of nuclear DNA across the contact zone beyond the distance of our nearest transect sites. This lack of introgression might be due to differences in the number of Robertsonian polymorphisms that occurs within *B. brevicauda* and *B. hylophaga* (Meylan 1967; Lee and Zimmerman 1969; Genoways et al. 1977; George et al. 1982; Oshida et al. 2003), which likely reduces fitness (Searle 1993). Several hybrid zone studies have documented limited introgression between species with chromosomal rearrangements (Bradley et al. 1991; Basset et al. 2007; Genoways et al. 2008). Hybrid zones in which hybrids have reduced fitness can reduce or impede introgression between species (Baker et al. 1989; Searle 1993; Baker and Bradley 2006), which maintains the integrity of parental gene pools despite interbreeding (Bigelow 1965; Baker et al. 1989). Problems during the pairing and segregation phases of meiosis caused by increased chromosomal heterozygosity can reduce hybrid fitness (Baker and Bickham 1986). This explanation seems highly plausible given the number of Robertsonian polymorphisms that occurs within *B. brevicauda* and *B. hylophaga* (Meylan 1967; Lee and Zimmerman 1969; Genoways et al. 1977; George et al. 1982; Oshida et al. 2003; Thompson and Hoffman 2009). Thus, the chromosomal rearrangements between *B. brevicauda* and *B. hylophaga* might be a strong isolating mechanism (Shaw et al. 1993; Benedict et al. 2006). Our observed lack of introgression supports the hypothesis that *B. brevicauda* and *B. hylophaga* represent distinct species under the genetic species concept of Baker and Bradley (2006). Given that, in Nebraska, hybridization seems to occur most extensively within a zone of no more than 2 km in width (Genoways and Choate 1972; Benedict 1999a, b), we expect that a similar narrow hybrid zone will be defined in our study area if sampling is done on a finer scale.

Distribution and conservation implications

Special consideration needs to be given to the more precisely defined distributional limits of *B. brevicauda* and *B. hylophaga* in the study area. Our results revealed that *B. hylophaga* is located only in the northwestern and southwestern extremes of Missouri and Iowa, respectively. It also appears that *B. brevicauda* could extend from Missouri into Kansas and be connected to the presumed isolated population of *B. brevicauda* (George et al. 1982; Moncrief et al. 1982; Benedict 1999b). This change in our understanding of the distributions of these species has potential conservation implications.

Blarina hylophaga has been identified by the Iowa Wildlife Action Plan as being a species of greatest conservation need (Zohrer et al. 2006) and is a target species for the Multiple Species Inventory and Monitoring Program by the Iowa Department of Natural Resources (Kinkead 2006). We have shown that the distribution of *B. hylophaga* in Iowa is re-

stricted to the southwestern counties of Fremont and Page. Bowles (1975) also found this species in adjacent Taylor County. Despite the limited distribution within the state, high densities have been reported previously in this area (Bowles 1975) and populations seemed to be in good condition during our fieldwork. Thus, *B. hylophaga* does not appear to be under significant conservation risk.

Acknowledgments

Portions of this research were supported by the Central Plains Society of Mammalogists and the Kansas Academy of Sciences. Additional funding came from the Fort Hays State University Department of Biological Sciences, Fort Hays State University Graduate School, and Tarleton State University Research Committee. Thanks also go to R.A. Benedict and M.J. Hamilton for advice in trapping and karyotyping, respectively. Additional thanks go to A.L. Sandquist, Iowa Department of Natural Resources, and Squaw Creek National Wildlife Refuge for providing housing. R.D. Bradley, R.B. Channell, E.T. Gillock, J.D. Hanson, R.N. Platt, and R.J. Zakrzewski reviewed an earlier draft of the manuscript.

Appendix A

The following list includes specimens of northern short-tailed shrew (*Blarina brevicauda*) and Elliot's short-tailed shrew (*Blarina hylophaga*) collected in this study. Voucher specimens are housed in the Sternberg Museum of Natural History, Fort Hays State University (MHP). Localities are arranged alphabetically by state, county, and specific locality. For specimen locality, localities are ordered by latitude from north to south and by longitude from west to east. The number of specimens collected from each locality is indicated.

Blarina brevicauda

IOWA — FREMONT COUNTY: 7 mi. W Tabor (T70N, R43W, NE 1/4 sec. 5) (40.90058 N, 95.80297 W), 4 (MHP 37676–37679); 2 mi. N, 3 1/4 mi. W Thurman (T70N, R43W, SE 1/4 sec. 20) (40.84878 N, 95.80919 W), 1 (MHP 37675). HARRISON COUNTY: 2 1/2 mi. S, 1 mi. W Woodbine (T80N, R42W, N central sec. 34) (41.70275 N, 95.72258 W), 10 (MHP 37651–37660). MILLS COUNTY: 5 mi. N, 3 3/4 mi. W Glenwood (T73N, R43W, SW 1/4 sec. 17) (41.12026 N, 95.81598 W), 3 (MHP 37680–37682); 6 3/4 mi. S, 1/4 mi. W Pacific Junction (T71N, R43W, W 1/2 sec. 28) (40.92325 N, 95.79880 W), 4 (MHP 37683–37686); 2 1/4 mi. W Pacific Junction (T72N, R44W, SE 1/4 sec. 24) (41.01994 N, 95.84222 W), 1 (MHP 37687).
