Statistical construction learning: Does a Zipfian problem space ensure robust language learning?

Nick C. Ellis and Matthew Brook O’Donnell

1. Introductory Overview

One of the key mysteries of language development is that each of us as learners has had different language experiences and yet somehow we have converged on broadly the same language system. From diverse, noisy samples, we end up with similar competence. How so? Some views hold that there are constraints in the learner’s estimation of how language works, as expectations of linguistic universals pre-programmed in some innate language acquisition device. Others hold that the constraints are in the dynamics of language itself – that language form, language meaning, and language usage come together to promote robust induction by means of statistical learning over limited samples. The research described here explores this question with regard English verbs, their grammatical form, semantics, and patterns of usage.

As a child, you engaged your parents and friends talking about things of shared interest using words and phrases that came to mind, and all the while you learned language. We were privy to none of this. Yet somehow we have converged upon a similar-enough ‘English’ to be able to communicate here. Our experience allows us similar interpretations of novel utterances like “the ball mandoolz across the ground” or “the teacher spugged the boy the book.” You know that mandool is a verb of motion and have some idea of how mandooling works – its action semantics. You know that spugging involves some sort of transfer, that the teacher is the donor, the boy the recipient, and that the book is the transferred object. How is this possible, given that you have never heard these verbs before? Each word of the construction contributes individual meaning, and the verb meanings in these Verb-Argument Constructions (VACs) is usually at the core. But the larger configuration of words has come to carry meaning as a whole too. The VAC as a category has inherited its schematic meaning from all of the examples you have heard. Mandool inherits its interpretation from the echoes of the verbs that occupy this VAC – words like come,
Knowledge of language is based on these types of inference, and verbs are the cornerstone of the syntax-semantics interface. To appreciate your idea of Phoebe, we would need a record of your relevant evidence (all of the dogs you have experienced, in their various forms and frequencies) and an understanding of the cognitive mechanisms that underpin categorization and abstraction. In the same way, if we want a scientific understanding of language knowledge, we need to know the evidence upon which such psycholinguistic inferences are based, and the relevant psychology of learning. These are the goals of our research. To describe the evidence, we take here a sample of VACs based upon English form, function, and usage distribution. The relevant psychology of learning, as we will explain, suggests that learnability will be optimized for constructions that are (1) Zipfian in their type-token distributions in usage (the most frequent word occurring approximately twice as often as the second most frequent word, which occurs twice as often as the fourth most frequent word, etc.), (2) selective in their verb form occupancy, and (3) coherent in their semantics. We assess whether these factors hold for our sample of VACs.

In summary, our methods are as follows; we will return to explain each step in detail. We search a tagged and dependency-parsed version of the British National Corpus (BNC 2007), a representative 100-million word corpus of English, for 23 example VACs previously identified in the Grammar Patterns volumes (Francis, Hunston, and Manning 1996; Hunston and Francis 1996) resulting from the COBUILD corpus-based dictionary project (Sinclair 1987). For each VAC, such as the pattern $V$(erb) $across$ $N$(oun phrase), we generate (1) a list of verb types that occupy each construction (e.g. walk, move, skitter). We tally the frequencies of these verbs to produce (2) a frequency ranked type-token profile for these verbs, and we determine the degree to which this is Zipfian (e.g. come 474 ... spread 146 ... throw 17 ... stagger 5; see Fig. 1 below). Because some verbs are faithful to one construction while others are more promiscuous, we next produce (3) a contingency-weighted list which reflects their statistical association (e.g. scud, skitter, sprawl, flit have the strongest association with $V$ across $N$). Because verbs are highly polysemous, we apply word sense disambiguation algorithms to assign (4) senses to these verbs in the sentences where they are present, according to WordNet (Miller 2009). We use techniques for identifying clustering and degrees of separation in networks to determine (5) the degree to which there is semantic cohesion of the verbs.

walk, move, ..., scud, skitter and flit – in just the same way that you can conjure up an idea of the first author’s dog Phoebe, who you have never met either, from the conspiracy of your memories of dogs.
occupying each construction (e.g., semantic fields TRAVEL and MOVE are
most frequent for V across N), and whether they follow a prototype/radial
category structure. In order to gauge the degree to which each VAC is
more coherent than expected by chance in terms of the association of its
grammatical form and semantics we generate a distributionally-yoked
control (a ‘control ersatz construction’, CEC), matched for type-token
distribution but otherwise randomly selected to be grammatically and
semantically uninformed. Through the comparison of VACs and CECS
of these various measures, and following what is known of the psychology
of learning, we assess the consequences for acquisition.

This work is a preliminary interdisciplinary test, across significantly
large language usage and learning corpora, of the generalizability of con-
struction grammar theories of language learning informed by cognitive
linguistics, learning theory, categorization, statistical learning, usage-based
child language acquisition, and complex systems theory.

2. Construction Grammar and Usage

Constructions are form-meaning mappings, conventionalized in the speech
community, and entrenched as language knowledge in the learner’s mind.
They are the symbolic units of language relating the defining properties of
their morphological, lexical, and syntactic form with particular semantic,
pragmatic, and discourse functions (Goldberg 2006, 1995). Verbs are central
in this: their semantic behavior is strongly intertwined with the syntagmatic
constraints governing their distributions. Construction Grammar argues
that all grammatical phenomena can be understood as learned pairings of
form (from morphemes, words, idioms, to partially lexically filled and
fully general phrasal patterns) and their associated semantic or discourse
functions: “the network of constructions captures our grammatical knowl-
edge in toto, i.e. it’s constructions all the way down” (Goldberg, 2006,
p. 18). Such beliefs, increasingly influential in the study of child language
acquisition, emphasize data-driven, emergent accounts of linguistic system-
iticities (e.g., Tomasello 2003; Clark and Kelly 2006).

Frequency, learning, and language come together in usage-based ap-
proaches which hold that we learn linguistic constructions while engaging
in communication (Bybee 2010). The last 50 years of psycholinguistic
research provides the evidence of usage-based acquisition in its demonstra-
tions that language processing is exquisitely sensitive to usage frequency at
all levels of language representation from phonology, through lexis and
syntax, to sentence processing (Ellis 2002). That language users are sensitive to the input frequencies of these patterns entails that they must have registered their occurrence in processing. These frequency effects are thus compelling evidence for usage-based models of language acquisition which emphasize the role of input. Language knowledge involves statistical knowledge, so humans learn more easily and process more fluently high frequency forms and ‘regular’ patterns which are exemplified by many types and which have few competitors (e.g., MacWhinney 2001). Psycho-linguistic perspectives thus hold that language learning is the associative learning of representations that reflect the probabilities of occurrence of form-function mappings.

If constructions as form-function mappings are the units of language, then language acquisition involves inducing these associations from experience of language usage. Constructionist accounts of language acquisition thus involve the distributional analysis of the language stream and the parallel analysis of contingent perceptuo-motor activity, with abstract constructions being learned as categories from the conspiracy of concrete exemplars of usage following statistical learning mechanisms (Christiansen and Chater 2001; Jurafsky and Martin 2000; Bybee and Hopper 2001; Bod, Hay, and Jannedy 2003; Ellis 2002; Perruchet and Pacton 2006) relating input and learner cognition.

3. Determinants of Construction Learning

Psychological analyses of the learning of constructions as form-meaning pairs is informed by the literature on the associative learning of cue-outcome contingencies where the usual determinants include: (1) input frequency (type-token frequency, Zipfian distribution), (2) form (salience and perception), (3) function (prototypicality of meaning), and (4) interactions between these (contingency of form-function mapping) (Ellis and Cadierno 2009). We will briefly consider each in turn, along with studies demonstrating their applicability:

3.1. Input Frequency

3.1.1. Construction Frequency

Frequency of exposure promotes learning and entrenchment (e.g., Anderson 2000; Ebbinghaus 1885; Bartlett [1932] 1967). Learning, memory and
perception are all affected by frequency of usage: the more times we experience something, the stronger our memory for it, and the more fluently it is accessed. The more recently we have experienced something, the stronger our memory for it, and the more fluently it is accessed [hence your reading this sentence more fluently than the preceding one]. The more times we experience conjunctions of features, the more they become associated in our minds and the more these subsequently affect perception and categorization; so a stimulus becomes associated to a context and we become more likely to perceive it in that context.

Frequency of exposure also underpins statistical learning of categories (Mintz 2002; Hunt and Aslin 2010; Lakoff 1987; Taylor 1998; Harnad 1987). Human categorization ability provides the most persuasive testament to our incessant unconscious figuring or ‘tallying’. We know that natural categories are fuzzy rather than monothetic. Wittgenstein’s (1953) consideration of the concept game showed that no set of features that we can list covers all the things that we call games, ranging as the exemplars variously do from soccer, through chess, bridge, and poker, to solitaire. Instead, what organizes these exemplars into the game category is a set of family resemblances among these members – son may be like mother, and mother like sister, but in a very different way. And we learn about these families, like our own, from experience. Exemplars are similar if they have many features in common and few distinctive attributes (features belonging to one but not the other); the more similar are two objects on these quantitative grounds, the faster are people at judging them to be similar (Tversky 1977). The greater the token frequency of an exemplar, the more it contributes to defining the category, and the greater the likelihood it will be considered the prototype. The operationalization of this criterion predicts the speed of human categorization performance – people more quickly classify as dogs Labradors (or other typically sized, typically colored, typically tailed, typically featured specimens) than they do dogs with less common features or feature combinations like Shar Peis or Neapolitan Mastiffs. Prototypes are judged faster and more accurately, even if they themselves have never been seen before – someone who has never seen a Labrador, yet who has experienced the rest of the run of the canine mill, will still be fast and accurate in judging it to be a dog (Posner and Keele 1970). Such effects make it very clear that although people don’t go around consciously counting features, they nevertheless have very accurate knowledge of the underlying frequency distributions and their central tendencies.
3.1.2. Type and Token Frequency

Token frequency counts how often a particular form appears in the input. Type frequency, on the other hand, refers to the number of distinct lexical items that can be substituted in a given slot in a construction, whether it is a word-level construction for inflection or a syntactic construction specifying the relation among words. For example, the “regular” English past tense -ed has a very high type frequency because it applies to thousands of different types of verbs, whereas the vowel change exemplified in *swam* and *rang* has much lower type frequency. The productivity of phonological, morphological, and syntactic patterns is a function of type rather than token frequency (Bybee and Hopper 2001). This is because: (a) the more lexical items that are heard in a certain position in a construction, the less likely it is that the construction is associated with a particular lexical item and the more likely it is that a general category is formed over the items that occur in that position; (b) the more items the category must cover, the more general are its criterial features and the more likely it is to extend to new items; and (c) high type frequency ensures that a construction is used frequently, thus strengthening its representational schema and making it more accessible for further use with new items (Bybee and Thompson 2000). In contrast, high token frequency promotes the entrenchedment or conservation of irregular forms and idioms; the irregular forms only survive because they are high frequency. There is related evidence for type-token matters in statistical learning research (Gómez 2002; Onnis et al. 2004). These findings support language’s place at the center of cognitive research into human categorization, which also emphasizes the importance of type frequency in classification.

3.1.3. Zipfian Distribution

In natural language, Zipf’s law (Zipf 1935) describes how the highest frequency words account for the most linguistic tokens. Zipf’s law states that the frequency of words decreases as a power function of their rank in the frequency table. If \( p_f \) is the proportion of words whose frequency in a given language sample is \( f \), then \( p_f \sim f^{-\gamma} \) with \( \gamma \approx 1 \). Zipf showed this scaling law holds across a wide variety of language samples. Subsequent research provides support for this law as a linguistic universal. Many language events across scales of analysis follow his power law: phoneme and letter strings (Kello and Beltz 2009), words (Evert 2005), grammatical constructs (Ninio 2006; O'Donnell and Ellis 2010), formulaic phrases (O'Donnell and Ellis 2009) etc. Scale-free laws also pervade language...
structures, such as scale-free networks in collocation (Solé et al. 2005; Bannard and Lieven 2009), in morphosyntactic productivity (Baayen 2008), in grammatical dependencies (Ferrer i Cancho & Solé, 2001, 2003; Ferrer i Cancho, Solé, & Köhler, 2004), and in networks of speakers, and language dynamics such as in speech perception and production, in language processing, in language acquisition, and in language change (Ninio 2006; Ellis 2008). Zipfian covering, where, as concepts need to be refined for clear communication, they are split, then split again hierarchically, determines basic categorization, the structure of semantic classes, and the language form-semantic structure interface (Steyvers and Tennenbaum 2005; Manin 2008). Scale-free laws pervade both language structure and usage. And not just language structure and use. Power law behavior like this has since been shown to apply to a wide variety of structures, networks, and dynamic processes in physical, biological, technological, social, cognitive, and psychological systems of various kinds (e.g. magnitudes of earthquakes, sizes of meteor craters, populations of cities, citations of scientific papers, number of hits received by web sites, perceptual psychophysics, memory, categorization, etc.) (Newman 2005; Kello et al. 2010). It has become a hallmark of Complex Systems theory. Zipfian scale-free laws are universal. Complexity theorists suspect them to be fundamental, and are beginning to investigate how they might underlie language processing, learnability, acquisition, usage and change (Beckner, et al., 2009; Ellis & Larsen-Freeman, 2009b; Ferrer i Cancho & Solé, 2001, 2003; Ferrer i Cancho, et al., 2004; Solé, et al., 2005) Various usage-based/functionalist/cognitive linguists (e.g., Boyd & Goldberg, 2009; Bybee, 2008, 2010; Ellis, 2008a; Goldberg, 2006; Goldberg, Casenhiser, & Sethuraman, 2004; Lieven & Tomasello, 2008; Ninio, 1999, 2006) argue that it is the coming together of these distributions across linguistic form and linguistic function that makes language robustly learnable despite learners’ idiosyncratic experience and the ‘poverty of the stimulus’.

In first language acquisition, Goldberg, Casenhiser & Sethuraman (2004) demonstrated that there is a strong tendency for VACs to be occupied by one single verb with very high frequency in comparison to other verbs used, a profile which closely mirrors that of the mothers’ speech to these children. They argue that this promotes language acquisition: In the early stages of learning categories from exemplars, acquisition is optimized by the introduction of an initial, low-variance sample centered upon prototypical exemplars. This low variance sample allows learners to get a fix on what will account for most of the category members, with the bounds
of the category being defined later by experience of the full breadth of
exemplar types.

In naturalistic second language (L2) acquisition, Ellis and Ferreira-
Junior (2009) investigated type/token distributions in the items comprising
the linguistic form of English VACs (VL verb locative, VOL verb object
locative, VOO ditransitive) and showed that VAC verb type/token dis-
tribution in the input is Zipfian and that learners first acquire the most
frequent, prototypical and generic exemplar (e.g. put in VOL, give in VOO,
etc.).

3.2. Function (Prototypicality of Meaning)

Categories have graded structure, with some members being better exem-
plars than others. In the prototype theory of concepts (Rosch and Mervis
1975; Rosch et al. 1976), the prototype as an idealized central description
is the best example of the category, appropriately summarizing the most
representative attributes of a category. As the typical instance of a cate-
gory, it serves as the benchmark against which surrounding, less represen-
tative instances are classified.

Ellis & Ferreira-Junior (2009) show that the verbs that L2 learners first
used in particular VACs are prototypical and generic in function (go for
VL, put for VOL, and give for VOO). The same has been shown for child
language acquisition, where a small group of semantically general verbs,
often referred to as light verbs (e.g., go, do, make, come) are learned early
(Clark 1978; Ninio 1999; Pinker 1989). Ninio (1999) argues that, because
most of their semantics consist of some schematic notion of transitivity
with the addition of a minimum specific element, they are semantically
suitable, salient, and frequent; hence, learners start transitive word com-
binations with these generic verbs. Thereafter, as Clark describes, “many
uses of these verbs are replaced, as children get older, by more specific
terms. . . . General purpose verbs, of course, continue to be used but become
proportionately less frequent as children acquire more words for specific
categories of actions” (p. 53).

3.3. Interactions between these (Contingency of Form-Function
Mapping)

Psychological research into associative learning has long recognized that
while frequency of form is important, so too is contingency of mapping
(Shanks 1995). Consider how, in the learning of the category of birds,
while eyes and wings are equally frequently experienced features in the
exemplars, it is wings which are distinctive in differentiating birds from other animals. Wings are important features to learning the category of birds because they are reliably associated with class membership, eyes are neither. Raw frequency of occurrence is less important than the contingency between cue and interpretation. Distinctiveness or reliability of form-function mapping is a driving force of all associative learning, to the degree that the field of its study has been known as ‘contingency learning’ since Rescorla (1968) showed that for classical conditioning, if one removed the contingency between the conditioned stimulus (CS) and the unconditioned (US), preserving the temporal pairing between CS and US but adding additional trials where the US appeared on its own, then animals did not develop a conditioned response to the CS. This result was a milestone in the development of learning theory because it implied that it was contingency, not temporal pairing, that generated conditioned responding. Contingency, and its associated aspects of predictive value, information gain, and statistical association, have been at the core of learning theory ever since. It is central in psycholinguistic theories of language acquisition too (Ellis 2008; MacWhinney 1987; Ellis 2006, 2006; Gries and Wulff 2005), with the most developed account for L2 acquisition being that of the Competition model (MacWhinney 1987, 1997, 2001).

Ellis and Ferreira-Junior (2009) use a variety of metrics to show that VAC acquisition is determined by their contingency of form-function mapping. They show that the one-way dependency statistic $\Delta P$ (Allan 1980) that is commonly used in the associative learning literature (Shanks 1995), as well as collostructional analysis measures current in corpus linguistics (Gries and Stefanowitsch 2004; Stefanowitsch and Gries 2003) predict effects of form-function contingency upon L2 VAC acquisition. Other researchers use conditional probabilities to investigate contingency effects in VAC acquisition. This is still an active area of inquiry, and more research is required before we know which statistical measures of form-function contingency are more predictive of acquisition and processing.

Ellis and Larsen-Freeman (2009) provided computational (Emergent connectionist) serial-recurrent network simulations of these various factors as they play out in the emergence of constructions as generalized linguistic schema from their frequency distributions in the input. This fundamental claim that Zipfian distributional properties of language usage helps to make language learnable has thus begun to be explored for these three VACs, at least. But three VACs is a pitifully small sample of English grammar. It remains an important research agenda to explore its generality across the wide range of the verb constructicon.
The primary motivation of construction grammar is that we must bring together linguistic form, learner cognition, and usage. An important consequence is that constructions cannot be defined purely on the basis of linguistic form, or semantics, or frequency of usage alone. All three factors are necessary in their operationalization and measurement. Psychology theory relating to the statistical learning of categories suggests that constructions are robustly learnable when they are (1) Zipfian in their type-token distributions in usage, (2) selective in their verb form occupancy, and (3) coherent in their semantics. Our research aims to assess this for a sample of the verbal grammar of English, analyzing the way VACs map form and meaning, and providing an inventory of the verbs that exemplify these constructions and their frequency.

4. Method

As a starting point, we considered several of the major theories and datasets of construction grammar such as FrameNet (Fillmore, Johnson, and Petruck 2003). However, because our research aims to empirically determine the semantic associations of particular linguistic forms, it is important that such forms are initially defined by bottom-up means that are semantics-free. There is no one in corpus linguistics who ‘trusts the text’ more than Sinclair (2004) in his operationalizations of linguistic constructions on the basis of repeated patterns of words in collocation, colligation, and phrases. Therefore we chose the definitions of VACs presented in the Verb Grammar Patterns (Hunston and Francis 1996) that arose out of the COBUILD project (Sinclair 1987) for our first analyses. We focus on a convenience sample of 23 constructions for our initial explorations here. Most of these follow the verb – preposition – noun phrase structure, such as V into N, V after N, V as N (Goldberg 2006), but we also include other classic examples such as the ditransitive, and the way construction (Jackendoff 1997).

4.1. Step 1 Construction Inventory: COBUILD Verb Patterns

The form-based patterns described in the COBUILD Verb Patterns volume (Francis, Hunston, and Manning 1996) take the form of word class and lexis combinations, such as V across N, V into N and V N N. For each of these patterns the resource provides information as to the structural configurations and meaning groups found around these patterns through detailed concordance analysis of the Bank of English corpus.
during the construction of the COBUILD dictionary. For instance, the
following is provided for the $V$ across $N$ pattern (Francis, Hunston, and
Manning 1996):

| The verb is followed by a prepositional phrase which consists of across and a
| noun group.
| This pattern has one structure:
| * Verb with Adjunct.
|  
| *I cut across the field.*

Further example sentences drawn from the corpus are provided and a list
of verbs found in the pattern and that are semantically typical are given.
For the $V$ across $N$ pattern these are: brush, cut, fall, flicker, flit, plane,
skim, sweep. No indication is given as to how frequent each of these types
are or how comprehensive the list of types is. Further structural (syntacti-
cal) characteristics of the pattern are sometimes provided, such as the fact
that for $V$ across $N$ the prepositional phrase is an adjunct and that the
verb is never passive. There are over 700 patterns of varying complexity
in the Grammar Patterns volume. In subsequent work we hope to analyze
them all in the same ways we describe here for our sample of 23.

4.2. Step 2 Corpus: BNC XML Parsed Corpora

To get a representative sample of usage, the analysis of verb type-token
distribution in the kinds of construction patterns described in Step 1
should be done across corpora in the magnitude of the tens or hundreds
of millions of words. Searching for the pattern as specified requires that
the corpora be part-of-speech tagged, and some kind of partial parsing
and chunking is necessary to apply the necessary structural constraints
(see Mason and Hunston 2004 for exploratory methodology). For this
initial work, we chose to use the 100 million word BNC (2007) on account
of its size, the breadth of text types it contains and the consistent lemmati-
ization and part-of-speech tagging. Andersen et al. (2008) parsed the XML
version of the BNC using the RASP parser (Briscoe, Carroll, and Watson
2006). RASP is a statistical feature-based parser that produces a probabil-
istically ordered set of parse trees for a given sentence and additionally
a set of grammatical relations that capture “those aspects of predicate-
argument structure that the system is able to recover and is the most stable
and grammar independent representation available” (Briscoe, Carroll, and
Watson 2006). For each VAC, we translate the formal specifications from
the COBUILD patterns into queries to retrieve instances of the pattern
from the parsed corpus.

4.3. Step 3 Searching Construction Patterns

Using a combination of part-of-speech, lemma and dependency constraints
we construct queries for each of the construction patterns. For example,
the \( V \) across \( N \) pattern is identified by looking for sentences that have a
verb form within 3 words of an instance of \( \text{across} \) as a preposition, where
there is an indirect object relation holding between \( \text{across} \) and the verb
and the verb does not have any other object or complement relations to
following words in the sentence. Table 1 shows our 23 constructions, the
number of verb types that occupy them, the total number of tokens found,
and the type-token ratio.

We have still to carry out a systematic precision-recall analysis, but the
strict constraints using the dependency relations provides us with a good
precision and the size of the corpus results in a reasonable number of
tokens to carry out distributional analysis. In future, we plan to use a
number of different parsers [e.g. Stanford (Klein and Manning 2003),
Pro3Gres (Schneider, Rinaldi, and Dowdall 2004), MALT (Nivre, Hall,
and Nilsson 2004), and Link (Grinberg, Lafferty, and Sleator 1995)] over
the same corpora and use a consensus-based selection method where
sentences will be counted if two or more parsers agree (according to queries
particular to their parsing output) that it is an instance of a particular con-
struction pattern. Further we will select samples of certain VAC distribu-
tions for manual evaluation.

4.4. Step 4 A Frequency Ranked Type-Token VAC Profile

The sentences extracted using this procedure outlined for each of the con-
struction patterns are stored in a document database. This database can
then be queried to produce verb type distributions such as those in Table
2 for the \( V \) across \( N \) VAC pattern. These distributions appear to be
Zipfian, exhibiting the characteristic long-tailed distribution in a plot of
rank against frequency. We have developed scripts in R (R Development
Core Team 2008) to generate logarithmic plots and linear regression to
examine the extent of this trend. Dorogovstev & Mendes (2003) outline the
use of logarithmic binning of frequency against log cumulative frequency
methods for measuring distributions of this type. Linear regression can be
applied to the resulting plots and goodness of fit \((R^2)\) and the slope \((\gamma)\)
Figure 1 shows such a plot for verb type frequency of the $V$ across $N$ construction pattern extracted from the BNC grouping types into 20 logarithmic bins according to their frequency. Each point represents one bin and a verb from each group is randomly selected to label the point with its token frequency in parentheses. For example, the type look occurs 102 times in the $V$ across $N$ pattern and is placed into the 15th bin with the types go, lie and lean. Points towards the lower right of the plot indicate high-frequency low-type groupings and those towards the top left low-frequency high-type groupings, that is the fat- or long-tail of the distribution.

Table 1. Type-Token data for 23 VACs drawn from COBUILD Verb Patterns retrieved from the BNC.
Figure 2 shows such the same type of plot for verb type frequency of the ditransitive $V N N$ construction pattern extracted and binned in the same way. Both distributions produce a good fit ($R^2 > 0.99$) with a straight regression line, indicating a Zipfian type-token frequency distributions.
for these constructions. Inspection of the construction verb types, from most frequent down, also demonstrates that, as in prior research (Ellis & Ferreira-Junior, 2009b; Goldberg, et al., 2004; Ninio, 1999, 2006), the lead member is prototypical of the construction and generic in its action semantics.

Figure 2. Verb type distribution for V N N
If Zipf’s law applies across language, then any sample of language will be Zipfian-distributed, rendering such findings potentially trivial (we elaborate on this in Step 7). But they become much more interesting if the company of verb forms occupying a construction is selective, i.e. if the frequencies of the particular VAC verb members cannot be predicted from their frequencies in language as a whole. We measure the degree to which VACs are selective like this using a variety of measures including a chi-square goodness-of-fit test, and the statistic ‘1-tau’ where Kendall’s tau measures the correlation between the rank verb frequencies in the construction and in language as a whole. Higher scores on both of these metrics indicate greater VAC selectivity. Another useful measure is Shannon entropy for the distribution. Entropy is a measure of the uncertainty associated with a random variable – it is affected by the number of types in the system and the distribution of the tokens of the types. If there is just one type, then the system is far from random, and entropy is low. If there are ten types of equal probability, the system is quite random, but if 99% of the tokens are of just one type, it is far less random, and so on. The lower the entropy the more coherent the VAC verb family. Construction scores on all these measures are given later in Table 4.

4.5. Step 5 Determining the Contingency between Verbs and VACs

Some verbs are closely tied to a particular construction (for example, *give* is highly indicative of the ditransitive construction, whereas *leave*, although it can form a ditransitive, is more often associated with other constructions such as the simple transitive or intransitive). As we described above, the more reliable the contingency between a cue and an outcome, the more readily an association between them can be learned (Shanks 1995), so constructions with more faithful verb members are more transparent and thus should be more readily acquired (Ellis 2006). The measures of contingency that we adopt here are (1) faithfulness – the proportion of tokens of total verb usage that appear this particular construction (e.g., the faithfulness of *give* to the ditransitive is approximately 0.40; that of *leave* is 0.01, (2) directional one-way associations, contingency (ΔP Construction → Word: *give* 0.314, *leave* 0.003) and (ΔP Word → Construction: *give* 0.025, *leave* 0.001) (e.g. Ellis & Ferreira-Junior, 2009), and (3) directional mutual information (MI Word → Construction: *give* 16.26, *leave* 11.73 and MI Construction → Word: *give* 12.61 *leave* 9.11), an information science statistic that has been shown to predict language processing fluency (e.g., Ellis, Simpson-Vlach, and Maynard 2008; Jurafsky...

</table>

2002). Table 2 lists some of these contingency measures for the verbs occupying the $V$ across $N$ VAC pattern.

It is instructive to reorder the distribution according to these measures and consider the top items in terms of how characteristic of the VAC semantics they are (this is a standard option for each VAC listed on the website we are developing to allow open-access to our analyses). For the $V$ across $N$ VAC pattern, more generic movement verbs come, walk, cut, run, spread and move top the list ordered by token frequency. But when ordered according to verb to construction faithfulness, the items are much more specific in their meaning, though of low frequency: scud, skitter, sprawl, flit, emblazon and slant. The average faithfulness, MI and ΔP scores across the members of the construction are also important metrics, illustrating the degree to which VACs are selective in their membership. We show examples later in Table 4.
4.6. Step 6 Identifying the Meaning of Verb Types Occupying the Constructions

We are investigating several ways of analyzing verb semantics. Because our research aims to empirically determine the semantic associations of particular linguistic forms, ideally the semantic classes we employ should be defined in a way that is free of linguistic distributional information, otherwise we would be building in circularity. Therefore distributional semantic methods such as Latent Semantic Analysis (LSA, Landauer et al. 2007) are not our first choice here. Instead, here we utilize WordNet, a distribution-free semantic database based upon psycholinguistic theory which has been in development since 1985 (Miller 2009). WordNet places words into a hierarchical network. At the top level, the hierarchy of verbs is organized into 559 distinct root synonym sets (‘synsets’ such as move1 expressing translational movement, move2 movement without displacement, etc.) which then split into over 13,700 verb synsets. Verbs are linked in the hierarchy according to relations such as hypernym [verb Y is a hypernym of the verb X if the activity X is a (kind of) Y (to perceive is an hypernym of to listen], and hyponym [verb Y is a hyponym of the verb X if the activity Y is doing X in some manner (to lisp is a hyponym of to talk)]. Various algorithms to determine the semantic similarity between WordNet synsets have been developed which consider the distance between the conceptual categories of words, as well as considering the hierarchical structure of the WordNet (Pedersen, Patwardhan, and Michelizzi 2004).

Polysemy is a significant issue of working with lexical resources such as WordNet, particularly when analyzing verb semantics. For example, in WordNet the lemma forms move, run and give used as verbs are found in 16, 41 and 44 different synsets respectively. To address this we have applied word sense disambiguation tools specifically designed to work with WordNet (Pedersen and Kolhatkar 2009) to the sentences retrieved at Step 3.

4.7. Step 7 Generating Distributionally-Matched, Control Ersatz Constructions (CECs)

Miller (1965) in his preface to the MIT Press edition of Zipf’s (1935) Psychobiology of Language claimed that Zipfian type-token frequency distributions are essentially uninteresting artifacts of language in use rather than important factors in acquisition. His “monkey at the typewriter” (1957) word generation model produces random words of arbitrary average length as follows: With a probability \( s \), a word separator is generated at
each step, with probability \((1 - s)/N\), a letter from an alphabet of size \(N\) is generated, each letter having the same probability. That the monkey at the typewriter model produces gibberish that is Zipfian well-distributed thence rendered Zipf’s law uninteresting for linguistics for several decades (see also Manning and Schütze 1999). Li (1992) reawakened the issue with further demonstrations that random texts exhibit Zipf’s law-like word frequency distributions. Ferrer-i-Cancho and Solé (2002) responded by showing that random texts lose the Zipfian shape in the frequency versus rank plot when words are restricted to a certain length, which is not the case in real texts. As they conclude: “By assuming that Zipf’s law is a trivial statistical regularity, some authors have declined to include it as part of the features of language origin. Instead, it has been used as a given statistical fact with no need for explanation. Our observations do not give support to this view.” Nevertheless Yang (2010) claims that item/usage-based approaches to language acquisition, which typically make use of the notion of constructions, have failed to amass sufficient empirical evidence and to apply the necessary statistical analysis to support their conclusions. He asserts that it is the Zipfian nature of language itself (the sparse data problem) that gives rise to apparent item-specific patterns. In response to these possibilities, for every VAC we analyze, we generate a distributionally-yoked control which is matched for type-token distribution but otherwise randomly selected to be grammatically and semantically uninformed. We refer to these distributions as ‘control ersatz constructions’ (CECs). We then assess, using paired-sample tests, the degree to which VACs are more coherent than expected by chance in terms of the association of their grammatical form and semantics. We show such comparisons for illustration VACs and their yoked CECs later in Tables 4, 5 and 6.

The goal in generating CECs is to produce a distribution with the same number of types and tokens as the VAC. To do this we use the following method. For each type in a distribution derived from a VAC pattern (e.g. walk in \(V\) across \(N\) occurs 203 times), ascertain its corpus frequency (walk occurs 17820 times in the BNC) and randomly select a replacement type from the list of all verb types in the corpus found within the same frequency band (e.g. from learn, increase, explain, watch, stay, etc. which occur with similar frequencies to give in the BNC). This results in a matching number of types that reflect the same general frequency profile as those from the VAC. Then, using this list of replacement types, sample the same number of tokens (along with their sentence contexts) as in the VAC distribution (e.g. 4889 for \(V\) across \(N\)) following the probability distribution of the replacement types in the whole corpus (e.g. walk, with...
a corpus frequency of 17820, will be sampled roughly twice as often as 
extend, which occurs 9290 times). The resulting distribution has an identical 
number of types and tokens its matching VAC, although, if the VAC does 
attract particular verbs, the lead members of the CEC distribution will 
have a token frequency somewhat lower than those in the VAC.

4.8. Step 8 Evaluating Semantic Cohesion in the VAC Distributions

We have suggested that an intuitive reading of VAC type-token lists such 
as in Table 2 shows that the tokens list captures the most general and 
prototypical senses (come, walk, move etc. for V across N and give, make, 
tell, offer for V N N), while the list ordered by faithfulness highlights 
some quite construction specific (and low frequency) items, such as scud, 
flit and flicker for V across N. Using the structure of the verb component 
of the WordNet dictionary, where each synset can be traced back to a root 
or top-level synset, we are able to compare the semantic cohesion of the 
top 20 verbs, using their disambiguated WordNet senses, from a given 
VAC to its matching CEC. So for each verb in a VAC or CEC we query 
the database for the disambiguated WordNet senses for the verb in the 
instance sentences. For example, in V across N, the verb type move occurs 
114 times across 5 synsets: move.v.1 (86x), move.v.2 (18x), move.v.3 (5x), 
move.v.7 (1x) and move.v.8 (4x). Each of these synsets can be traced back 
to a top or root level synset or may itself be that synset: move.v.1 → 
travel.v.1, move.v.2 → move.v.2, move.v.3 → move.v.3, move.v.7 → 
change.v.3, move.v.8 → act.v.1. Table 3 shows this for the V across N 
VAC pattern, where the synsets come.v.1, walk.v.1, run.v.1, move.v.1, 
go.v.1, fall.v.2, pass.v.1, travel.v.1, stride.v.1, stride.v.2 account for 744 of 
the 4889 (15%) tokens, and share the top level hypernym synset travel.v.01. 
In comparison, the most frequent root synset for the matching CEC, pro-
nounce.v.1, accounts for just 4% of the tokens. The VAC has a much 
more compact semantic distribution, in that 5 top level synsets account 
for a third of the tokens compared to the 21 required to account for the 
same proportion for the CEC.

We have explored two methods of evaluating the differences between 
the semantic sense distributions, such as the one in Table 3, for each 
VAC-CEC pair. First, we can measure the amount of variation in the 
distribution (i.e. its compactness) using Shannon entropy as we did in 
Step 4. For these semantic distributions this can be done according to (1) 
number of sense types per root (V across N VAC: 2.75 CEC: 3.37) (so 
ignoring the token frequency column in Table 3) and (2) the token fre-

quency per root (\(V\) across N VAC: 2.08 CEC: 3.08), the lower the entropy
the more coherent the VAC verb semantics. These figures are calculated
for all 23 VACs and CECs and shown in Tables 4 and 5 as (1) Type
entropy per root synset and (2) Token entropy per root synset. Secondly,
we can develop the observation for the distribution in Table 3 that the
top three root synsets, in the VAC account for 25% (1236) of the tokens
compared to 11% (530) for the CEC. Third, we quantify the semantic
coherence or ‘clumpiness’ of the disambiguated senses for the top 20 verb
forms in the VAC and CEC distributions using measures of semantic
measures in their Perl WordNet::Similarity package, three (path, lch and
\(wup\)) based on the path length between concepts in WordNet Synsets and
three (\(res\), jcn and \(lin\)) that incorporate a measure called ‘information con-
tent’ related to concept specificity. For instance, using the \(res\) similarity
measure (Resnik 1995) the top 20 verbs in \(V\) across N VAC distribution
have a mean similarity score of 0.353 compared to 0.174 for the matching
CEC.

5. Results

Our core research questions concern the degree to which VAC form, func-
tion, and usage promote robust learning. As we explained in the theoretical
background, the psychology of learning as it relates to these psycholinguistic
matters suggests, in essence, that learnability will be optimized for con-
structions that are (1) Zipfian in their type-token distributions in usage, (2)
selective in their verb form occupancy, (3) coherent in their semantics.
Their values on the metrics we have described so far are illustrated for
the 23 VACs in Table 4 along with those for their yoked CECs in Table 5.
Table 6 contrasts between the VACs and the CECs on these measures
as the results of paired-sample t-tests.

The results demonstrate:

5.1. Type-token Usage Distributions

All of the VACs are Zipfian in their type-token distributions in usage
(VACs: \(M_\gamma = -1.00, MR^2 = 0.98\)). So too are their matched CECs
(\(M_\gamma = -1.12, MR^2 = 0.96\)). The fit is slightly better for the VACs than
the CECs because the yoked-matching algorithm tends to make the
topmost types of the CEC somewhat less extreme in frequency than is
found in the real VACs (because particular verbs are attracted to particular

VACs), and so the fit line is not pulled out into so extreme a tail. Inspection of the graphs for each of the 23 VACs shows that the highest frequency items take the lion’s share of the distribution and, as in prior research (Ellis & Ferreira-Junior, 2009b; Goldberg, et al., 2004; Ninio, 1999, 2006), the lead member is prototypical of the construction and generic in its action semantics (see the rightmost column in Table 1).

5.2. Family Membership and Type Occupancy

VACs are selective in their verb form family occupancy. There is much less entropy in the VACs than the CECs, with fewer forms of a less evenly-distributed nature ($M$ distribution Entropy VAC 4.97, CEC 5.54, $p < .0001$). The distribution deviation from verb frequency in the language as a whole is much greater in the VACs than the CECs ($M \chi^2$ VAC 69411, CEC 698, $p < .0001$). The lack of overall correlation between VAC verb frequency and overall verb frequency in the language is much greater in the VACs ($M 1 - \tau$ VAC 0.76, CEC 0.21, $p < .002$).

Individual verbs select particular constructions ($M \text{MI}_{w-c}$ VAC 14.16, CEC 12.80, $p < .01$) and particular constructions select particular words ($M \text{AP}_{c-w}$ VAC 0.006, CEC 0.004, $p < .0001$). Overall then, there is greater contingency between verb types and constructions.

5.3. Semantic Coherence

VACs are coherent in their semantics with lower type ($M$ VAC 3.10, CEC 3.51, $p < .0001$) and token ($M$ VAC 2.41, CEC 3.08, $p < .0001$) sense entropy. Figure 3 shows distributions of the root synsets for the top 20 types of each of the VAC-CEC pairs through plots of logarithmic token frequency against rank – in each pair, fewer senses cover more of the VAC uses than the CEC. Figure 3 also shows the proportion of tokens accounted for by the top three root synsets (e.g. for $V$ across $N$: VAC 0.25 CEC 0.11). The proportion of the total tokens covered by their three most frequent WordNet roots is much higher in the VACs ($M$ VAC 0.26, CEC 0.11, $p < .0001$). Finally, the VAC distributions are higher on the Pedersen semantic similarity measures ($M$ lch VAC 0.13, CEC 0.09, $p < .0002$) ($M$ res VAC 0.24, CEC 0.22, $p < .0001$).

6. Discussion

Twenty-three constructions is a better sample of constructions than three, and the 16,141,058 tokens of verb usage analyzed here is a lot more representative than the 14,474 analyzed in Ellis & Ferreira-Junior (2009a,b).
Figure 3. Distribution of WordNet root verb synsets for VACs and CECs
Nevertheless, the conclusions from those earlier studies seem to generalize. We have shown:

- The frequency distribution for the types occupying the verb island of each VAC are Zipfian.
- The most frequent verb for each VAC is much more frequent than the other members, taking the lion’s share of the distribution.
- The most frequent verb in each VAC is prototypical of that construction’s functional interpretation, albeit generic in its action semantics.
- VACs are selective in their verb form family occupancy:
  - Individual verbs select particular constructions.
  - Particular constructions select particular verbs.
  - There is greater contingency between verb types and constructions.
- VACS are coherent in their semantics.

Psychology theory relating to the statistical learning of categories suggests that these are the factors which make concepts robustly learnable. We suggest, therefore, that these are the mechanisms which make linguistic constructions robustly learnable too, and that they are learned by similar means.

7. Future Work

7.1. An Exhaustive Inventory of English VACs

This is still a small sample from which to generalize. In subsequent work we intend to analyze the 700+ patterns of Verb Pattern Grammar volume as found in the 100 million words of the BNC. Other theories of construction grammar start from different motivations, some more semantic [e.g. Framenet (Fillmore, Johnson, and Petruck 2003) and VerbNet (Kipper et al. 2008; Palmer 2010; Levin 1993)], some alternatively syntactic [e.g. the Erlangen Valency Patternbank (Herbst and Uhrig 2010; Herbst et al. 2004)], and so present different, complementary descriptions of English verb grammar. Given time, we hope to analyze usage patterns from these descriptions too. We are particularly interested in whether these inventories represent optimal partitioning of verb semantics, starting with basic categories of action semantics and proceeding to greater specificity via Zipfian mapping.

7.2. Learner Language

We are also interested in extending these approaches to learner language to investigate whether first and L2 learners’ acquisition follows the same
construction distributional profiles. We have done some initial pilot work to test the viability of our methods by extracting 18 of the same VAC patterns from American English and British English child language acquisition corpora in CHILDES (MacWhinney 2000, 2000) transcripts. Child directed speech (CDS, over 6.8 million words) was separated from the speech of the target child (over 3.6 million words) for the UK and USA components of the database where dependency parsing of each utterance is available (Sagae et al. 2007). The same analysis steps described here are equally viable with learner language. In our initial explorations (O’Donnell and Ellis submitted) we build on the types of analysis carried out in Goldberg, Casenhiser & Sethuraman (2004) that demonstrate how the frequency profiles of CDS are reproduced in child language. For example, for the V across N VAC pattern go is the most frequent type in both CDS and child speech. Likewise, for V over N we found go and jump as the first types in both samples. For V with N the top 4 types, play, go, do, come, are shared, as they are for V under N: go, look, get, hide and the top two for V like N: look and go. The nature of CDS with respect to more general English can also be examined. Applying the various contingency and semantic measures discussed above we found the 10 most faithful types to the VAC pattern V like N were: 1) from the BNC: glitter, behave, gleam, bulge, shape, flutter, glow, shine, sound, sway (with a wup similarity score of 0.3559) and 2) for CDS: sound, act, shape, smell, taste, look, yell, feel, talk, fit (wup 0.4564). This initial analysis points both to the more frequent use of generic verbs (e.g. go and do) in CDS and a tighter semantic coherence in the items most associated with specific VACs. These steps need next to be done for the complete inventory of VACs so that a comparison can be made of general usage (BNC), CDS, and child language acquisition at different stages.

7.3. Determinants of Learning

Once we have these parallel datasets of sufficient scale, we can undertake a principled empirical analysis of the degree to which the psychological factors outlined really do determine acquisition. For each VAC in the input we will have the data relating to frequency, distributional, contingency, and semantic factors which learning theory considers important in acquisition. With the staged child language acquisition analyzed in the same way, we can test out these predictions and explore how the different factors conspire in the emergence of language.
7.4. Modeling Acquisition

As we have argued in an upcoming review of statistical corpus linguistics and language cognition (Ellis in press), the field as a whole needs to work on how to combine the various corpus metrics that contribute to learnability into a model of acquisition rather than a series of piecemeal univariate snapshots. We have developed some connectionist methods for looking at this and trialed them with just the three VACs VL, VOL, and VOO (Ellis and Larsen-Freeman 2009), but that enterprise and the current one are of hugely different scales. We need models of acquisition that relate such VAC measures as applied to the BNC and CDS to longitudinal patterns of child language and L2 acquisition.

8. Conclusion

This research shows some promise towards an English verb grammar operationalized as an inventory of VACs, their verb membership and their type-token frequency distributions, their contingency of mapping, and their semantic motivations. Our initial analyses show that constructions are (1) Zipfian in their type-token distributions in usage, (2) selective in their verb form occupancy, and (3) coherent in their semantics. Psychology theory relating to the statistical learning of categories suggests that these are the factors which make concepts robustly learnable. We suggest therefore, that these are the mechanisms which make linguistic constructions robustly learnable too, and that they are learned by similar means.

9. Epilogue

Phoebe was a black and brindle collie-cross (Figure 4). She was 12 years old when we brought her to (VOL_to) the US. It was Michigan, February, blue skies over 12\(\text{\textdegree}\) of snow. We collected her, dehydrated, from (VOL_from) DTW, left the airport, and pulled onto (VL_on) the nearest safe verge to let her out (VOL_out) of her travel-kennel. It had been a long flight and we were somewhat concerned, but after a typically warm reunion, she looked at (VL_at) the strange whiteness, and then, like a wolf pouncing on (VL_on) a mouse, she ponked into (VL_into) the snow.
